### Discussion of Results.

#### 1. Binary Mixtures from Benzene, Toluene and *m*-Cresol.

Examination of Table V. shows that, for all properties, slight deviations from the mixture rule are obtained, even for such chemically similar pairs of liquids as benzene and toluene. Density deviations at 28° C., were for all mixtures greater than for the lower temperature, 25° C. The results for these three mixtures show a close similarity in the direction of the deviation obtained in the case of most of these properties. The deviations in density, refractive index and magnetic mass susceptibility for the mixtures of the hydrocarbons with *m*-cresol are all of the same sign, indicating that the causes of deviation are probably similar for these properties, in both mixtures. Benzene and *m*-cresol mixtures show greater deviations in all properties than do toluene and *m*-cresol. This suggests that when other factors, such as chemical dissimilarity, are absent, the deviations are smaller the closer the molecular weights of the components are to one another. It seems also likely that the smaller deviation on mixing toluene and *meta*-cresol can be accounted for by the greater similarity of their molecular structure, that is, the presence of the methyl group in both. The shape of the toluene molecule would thus be more like that of the cresol, than would that of benzene.

#### 2. Binary Mixtures from Aniline, Nitrobenzene and *m*-Cresol.

A marked change of colour was observed on mixing aniline and nitrobenzene, even in the absence of light, suggesting that some considerable change had taken place on mixing these liquids. The deviations obtained, however, were no greater than for other mixtures, indicating that any change is due to association, rather than to a definite chemical combination. The nitrobenzene—*m*-cresol mixture appears to be nearly ideal, a somewhat unexpected result in view of the nature of the constituent molecules. Unlike the first group of mixtures, there seems in these three sets of mixtures to be no simple common factor causing deviations since Table V. shows no relationship between the direction of the deviations for the properties investigated. It must therefore be concluded that deviations here are due to more than one determining factor.

**General.**

The most important general result brought out by a consideration of columns 4 and 6 of Table V. is that for the six sets of mixtures the molar magnetic susceptibility is more nearly an ideal property than the mass susceptibility from which it is calculated. This is fully in keeping with the theoretical view that diamagnetic susceptibility is a fundamental atomic property.

**Summary.**

(1) The density, refractive index, heat of mixing, specific heat and magnetic mass susceptibility of a series of mixtures of the liquids benzene, toluene, *m*-cresol, aniline and nitrobenzene have been measured.

(2) None of the pairs of liquid mixtures can be considered as ideal with the possible exception of the nitrobenzene—*m*-cresol mixture which showed least deviation from the mixture law.

(3) Similar deviations were obtained for different properties for mixtures of benzene and toluene, respectively, with *m*-cresol, the wider apart the molecular weights of the constituents the more marked the deviation.

(4) For mixtures of nitrobenzene and aniline, respectively, with *meta*-cresol, no general rule governing the deviation of the properties investigated could be discovered.

(5) The molar magnetic mass susceptibility proved to be a more nearly additive property than any other property investigated.

The authors desire to express their thanks to Miss J. Cattermole, for carrying out the measurements of refractive index, density at 28°, specific heat and heat of mixing recorded in this paper.

One of us (V. C. G. T.), desires to express thanks to the Council of the Chemical Society for a grant which partially defrayed the cost of materials.

## CALCULATION OF THE RATE OF ELEMENTARY REACTIONS OF LIGHT AND HEAVY HYDROGEN.

BY L. FARKAS AND E. WIGNER.

*Received 15th January, 1936.*

### 1.

The reactions which will be the subject of the present paper are as follows :

The first two reactions determine the rate of homogeneous thermal conversion of light and heavy *para-ortho*-hydrogen. The mechanism of the homogeneous thermal conversion of light *para*-hydrogen into ordinary hydrogen has been cleared up in an important paper by A. Farkas.<sup>1</sup> The rates of reaction (2) together with those of (3) and (4) have been measured recently by A. and L. Farkas<sup>2</sup> and compared with each other on the basis of the usual theory of collision numbers. In the present paper we shall compute the reaction rate of the *elementary reactions* (1) to (4) on the basis of more recent theories<sup>3, 4, 5</sup> since, so far, these are the only examples providing both theoretical and experimental data for a comparison.

It will be interesting to calculate theoretically the number of interchanges which take place per unit time and volume (sec. litre) and unit concentration (mol./litre) of the reagents (H and H<sub>2</sub> *e.g.*). We designate as interchange a reaction involving atoms and molecules of the general type

where A, B and C represent H or D atoms. The rate of interchange can be measured directly, in principle, in cases (3) and (4). In reaction (1) only the rate of conversion :

can be measured directly. In the number of interchanges, as defined before, however, the reaction :

should also be counted. The number of these is 1/3 of those which lead to the *ortho*-molecule, strictly according to their statistical weights.<sup>6</sup> The total number of atomic interchanges is, thus, 4/3 times the number of *para-ortho*-conversions. Similarly the number of interchanges in case (2) is three times greater than the number of *ortho-para*-conversions, which can be measured directly in this case.<sup>2</sup>

The results for the rates of the first two interchange reactions are as follows :

TABLE I.

<sup>7</sup> K. H. Geib and P. Harteck, *Z. physik. Chem.*, 1931, *Bodensteinband*, p. 849.

The original concentration of  $H_2$  will be denoted by  $c$ . Since the concentration of  $D_2$  was in all experiments practically equal to that of  $H_2$ , the momentary concentration are  $[HD] = 2cy$ , that of

$$[H_2] = [D_2] = c(1 - y)$$

Thus we have finally the following equation :

$$[H] + [D] = \sqrt{Kc} \cdot \sqrt{1 - y} \cdot \sqrt{1 + 0.57 + 1.57 \frac{y}{1 - y}} \approx 1.25 \sqrt{Kc} \quad (9)$$

This means that the total concentration of atoms is hardly changing at all during the reaction. The numerical value for  $[H] + [D]$  is the same as hitherto used.<sup>3</sup> We assume furthermore that the ratio  $[H]/[D]$  is always  $k_3/k_4$  as in the beginning of the reaction.

The kinetic equation for the rate of formation of HD is then

$$2c \frac{dy}{dt} = (k_3[D] + k_4[H])c(1 - y) - (k_1[H] + k_2[D])2cy \quad (10)$$

Integrated, this gives

$$y_\infty - y_t = \frac{a}{b} \cdot e^{-bt} \quad (11)$$

where  $a = \frac{1}{2}(k_3[D] + k_4[H])$  and  $b = (\frac{1}{2}k_3 + k_2)[D] + (\frac{1}{2}k_4 + k_1)[H]$ . Introducing the calculated values of  $[H]$  and  $[D]$  and expressing  $k_3$  and  $k_4$  by  $k_3$  and  $k_4$  and the equilibrium constant<sup>2</sup> of the reactions (3) and (4) we have

$$a = \frac{1.25 \cdot \sqrt{Kc} k_3 k_4}{k_3 + k_4} \quad (12)$$

$$b = \frac{1.25 \sqrt{Kc}}{k_3 + k_4} \cdot (k_3 k_4 + 0.38 k_3^2 + 0.67 k_4^2) \quad (13)$$

The time of half-change of the reaction is determined by  $b$ . According to the experiments<sup>3</sup> this time of half-change is 1.5 times greater than that of reaction (1) at the same pressure and temperature (in the region 800°-1000°). Thus

$$b = \frac{k_1 \sqrt{K_1 2c}}{1.5} \quad (14)$$

The factor 2 enters under the square root because at the same pressure the concentration of  $H_2$  is twice as great in pure  $H_2$  (as used for reaction (1)) than it is in the mixture used for the reaction (3) and (4).

Hence we have

$$0.75 k_1 = \frac{k_3 k_4 + 0.38 k_3^2 + 0.67 k_4^2}{k_3 + k_4} \quad (15)$$

which is the only equation for  $k_3$  and  $k_4$  derivable under the above mentioned approximations from the present experiments. Into this equation we shall insert the theoretically calculated values of  $k_3$  and  $k_4$  and see whether it checks.

According to the usual collision number theory, the rate of reaction should vary with the temperature

$$k = 6.06 \cdot 10^{30} \left( \frac{d_a + d_m}{2} \right)^2 \sqrt{\frac{8RT(M_a + M_m)}{\pi M_a M_m}} \cdot S \cdot e^{-W/RT} \quad (16)$$

Here  $d_a$  and  $d_m$  are the diameters of the colliding particles (atom and molecule),  $M_a$  and  $M_m$  their masses.  $S$  is a steric factor,  $W$  the heat of activation. For reaction (1) in the temperature region 873°-1023° abs.

one obtains for  $W = 5500$  cal.,  $S = 0.07$ . In the low temperature region the figures are  $W = 7000$  cal.,  $S = 0.13$ . Although this is not very unsatisfactory it is obvious that the formula, using rather crude assumptions of the kinetic theory of gases and containing two arbitrary constants  $S$  and  $W$ , cannot represent the true state of affairs, since a *strict calculation of the reaction velocity constant must be based on the general methods of statistical mechanics.*

## 2.

A real theory of reaction rates should contain no arbitrary constant at all. Attempts in this direction were made in the following way. London<sup>8</sup> first introduced the idea of the energy surface. The configuration of a set of atoms (the three H's in (1)) can be described by the distances between them. The energy of the atoms in a configuration is thus a function of their distances

$$E = F(r_{12} r_{13} r_{23})$$

from which their motion during the reaction can be determined to a good approximation by classical mechanics. Classical mechanics can be applied because of the comparatively large masses of the nuclei. The equation of motion, e.g., in the  $x$  co-ordinate is

$$M \cdot \frac{\partial^2 x}{\partial t^2} = - \frac{\partial E}{\partial x}$$

It should be emphasised that  $E$  can be calculated only by quantum mechanics and that it contains the energy which the electrons have if the configuration is characterised by  $r_{12}$ ,  $r_{13}$ ,  $r_{23}$ . Since this energy *does not depend on the masses of the nuclei, the energy surface is the same for reactions 1 to 4.* Of course there are, according to the different quantum states of the electrons, many such energy surfaces, but here, in case of chemical reactions, we shall be concerned with the lowest one only.

In Fig. 1 which is taken from the work of Eyring and Polanyi<sup>9</sup> the contour lines of the energy surface of three H atoms are plotted for a straight configuration  $r_{13} = r_{12} + r_{23}$ , atom 2 being in the middle. *The angle between the axes  $r_{12}$  and  $r_{23}$  is chosen in such a way that the free motion (motion under the influence of the gravity) of a small heavy ball on the surface of Fig. 1 corresponds to the motion of the atoms in a straight line.*<sup>10</sup> The valley on the right of the figure corresponds to a molecule formed by the atoms 2 and 3 ( $r_{23}$  small) 1 being free. The valley towards the top of the figure corresponds to the molecule formed by the atoms 1 and 2, 3 being free. If the system performs the reaction

the point representing the state of the system must go somehow from the top valley to the valley in the right. The dotted line represents one such path. The following is the picture given by London for exchange reactions.

<sup>8</sup> London, *Sommerfeld Festschrift*, S. Hirzel, 1928, p. 104.

<sup>9</sup> Eyring and Polanyi, *Z. physik. Chem.*, 1931, 12B, 279.

<sup>10</sup> Professor O. K. Rice has kindly pointed out that this angle is  $60^\circ$  for three equal masses, instead of  $120^\circ$ , since the sign in formula (25) *Z. physik. Chem.*, 1931, 12B, 279 is incorrect.

The energy of the system is the energy of the heavy ball and it is evident that for very low energies a passage from one valley into the other is impossible. Only if the energy of the system exceeds a certain limit—that of point  $x$  in our figure—is such a passage possible. *Points  $x$  are the highest points of that path leading from one valley into the other, for which the highest point is as low as possible.* Generally this path has only one highest point—its energy is the activation energy—only in our symmetrical example there are two equally high points. The system in the activation point is called the “activated complex” or simply “complex.” It is evident therefore that the activation energy is given, if the energy surface is known, and this was aimed at in the pioneer work of Eyring and Polanyi.<sup>9</sup> It should be emphasised, however, that the present more accurate experimental data make more exact calculations desirable. Of course Fig. 1 represents, as already mentioned, the energy surface only for the straight configurations. For all configurations a three-dimensional surface would be necessary, but nothing would be changed fundamentally.

FIG. 1.

If we consider a system of three atoms in a finite box, the energy surface must be cut off at a certain point corresponding to the size of the box. The ball on our energy surface would roll around for some time in one valley, would pass over into the other, etc. The number of passages per unit time is equal to the number of atomic interchanges.

It is not easy to calculate this number exactly. It is quite possible, however, as we shall see, to calculate the number of passages over the lines through the activation points  $x$ , where the energy surface forms a saddle. Now, in our case not every passage over a saddle will lead to an atomic interchange. After every passage through one of the saddles the ball will roll around in the little hole of the middle of the figure and after a certain time may go on into the second valley or else may return to the initial one. The relative probability of the first event will be the ratio of the number of atomic interchanges to the number of passages through the saddle.

Although the number of passages through the saddles will be

calculated sufficiently accurately this ratio can be estimated only. It is evidently rather near to  $\frac{1}{2}$  in case the atoms 2 and 3 are equal, because the ball in the hole will go out in both directions with equal probability. If the atoms 2 and 3 are different (one D, the other H), though the potential surface is unaltered by this fact, the passage through both the barriers is for some quantum theoretical reasons not equally probable over the two saddles. We shall return to this point later. In this case the number of atomic interchanges will be only slightly smaller than the number of passages over the saddle which is more difficult to cross.

## 3.

The calculation of the number of passages through a given saddle can be performed by the so-called transition state method.<sup>11</sup> *A small strip in phase space is considered perpendicular to the direction of the ball's motion during the reaction. The probability of the ball being in this strip can be calculated by ordinary statistical mechanics. In the classical theory this probability is given by*

$$\eta = \frac{\int_{\text{strip}} ds e^{-V/kT}}{\int_{\text{vol.}} d\tau e^{-V/kT}}$$

In the numerator the integration must be extended over the strip, in the denominator over the whole phase space,  $V$  is the (potential) energy. The number of passages is obtained by multiplying this quantity by the mean component of the velocity of the ball which is perpendicular to the strip, and dividing by the width of the strip.

This classical theory must be corrected, of course, for quantum effects. There is the zero point energy, the quantum-mechanical leakage through the barriers and finally the jump from one energy surface to the other, which must be taken into account.

The formula which takes the first two effects into account\* and is valid for exchange reactions in which the activated complex is straight is:

$$k = \gamma \frac{1}{2} \left( \frac{M_a + M_m}{M_a M_m} \right)^{3/2} \frac{I_c}{I_m} \cdot \left( \frac{h}{2\pi} \right)^2 \cdot \sqrt{\frac{2\pi}{kT}} \cdot e^{-Q/RT} \cdot \frac{N_L}{1000} \\ \times \frac{\sinh \beta \nu_m}{(\sinh \beta \nu_a)^2 \sinh \beta \nu_s} \cdot (1 + \frac{1}{2} \beta^2 \nu_s^2) \quad (17)$$

Here,  $M_a$  and  $M_m$  are the masses of the colliding atom and molecule respectively.  $I_c$  is the moment of inertia of the activated complex,  $I_m$  that of the molecule,  $Q$  the activation energy,  $N_L$  the Avogadro number,  $\beta = \frac{h}{2kT}$ ,  $\nu_m$  is the vibrational frequency of the molecule which corresponds to 12 500 cal./mole energy in  $H_2$  and 8900 cal./mole in  $D_2$ ,

<sup>11</sup> For the history of this method, cf. Evans and Polanyi, *Trans. Faraday Soc.*, 1935, 31, 875.

\* This formula is identical with that derived by Pelzer and Wigner<sup>3</sup> and Wigner,<sup>4</sup> and is practically identical with that of Eyring.<sup>5</sup> Eyring's formula, however, does not contain the zero point energy of the complex explicitly and also neglects the leakage through the barrier.

$\nu_d$  is the deformational frequency of the complex and  $\nu_s$  the other stable frequency of the complex, whereas  $\nu_i$  is the imaginary frequency of the same:  $\nu_i$  can be calculated from the curvature of the potential surface in the same way as the real frequencies, except that the second derivative of the potential surface which is negative in this direction must be taken with the positive sign.  $k$  is the reaction velocity constant in mole/litre sec.;  $\gamma$  is the above discussed ratio of the number of atomic interchanges to the number of passages through one of the saddles.

The first line of formula (17) takes into account the classical quantities only, the second one contains the effect of the zero point energy of both the molecule and the complex and the effect of quantized vibrational levels. In

$$\frac{1}{2\sinh \beta \nu} = \frac{e^{-\hbar\nu/2kT}}{1 - e^{-\hbar\nu/kT}}$$

the numerator is due to the zero point energy  $\frac{1}{2}\hbar\nu$ , the denominator is the sum of states for the vibrational states.\* The last factor  $(1 + \frac{1}{2}\beta^2\nu_i^2)$  contains the "tunnel" effect. In consequence of the negative curvature of the energy surface perpendicular to the strip, some passages will occur by leakage even if the energy of the ball is not high enough to reach the activation point. This manifests itself in the last factor virtually as a negative zero point energy of the activated complex, as it facilitates the reaction.

The deformation frequency is doubly degenerate and  $\nu_d$  enters as a squared term into (17). A straight 3 atomic molecule has 4 vibrational ( $\nu_d, \nu_d, \nu_s, \nu_s$ ) 2 rotational and 3 translational degrees of freedom, altogether 9 degrees of freedom.

If the energy surface of § 2 is known all quantities entering into (17) may be calculated, thus (17) differs considerably from the formula of kinetic theory. The activation energy  $Q$  is the difference between the potential energy of the activation point and the bottom of the valley from which the reaction starts (without zero point energies).

For the calculation of vibrational frequencies, the potential energy in the neighbourhood of the activation point must be known up to the second power terms of the distances. This will be assumed to have the form:

$$\begin{aligned} V &= Q + p(r_{23} - 0.85)^2 - q(r_{12} - 1.25)^2 + s\delta^2 \\ &= Q + p\xi^2 - q\eta^2 + s\delta^2 \end{aligned} \quad (18)$$

the activation point having the co-ordinates  $r_{23} = 0.85$  Å,  $r_{12} = 1.23$  Å,  $\delta$  is the deformation angle 123. The fact that no  $(r_{12} - 1.25)(r_{23} - 0.85)$  term enters is not evident, *a priori*; but can be seen from the figure,  $p, q, s$  are positive constants the values of which can be derived from the Fig. 1.

For the vibrations,<sup>12</sup>  $\nu_i$  and  $\nu_s, \delta = 0$  can be assumed and the molecule put into the  $x$ -axis. The kinetic energy can be written then if we denote by  $M_1, M_2$  and  $M_3$  the masses of the three atoms

$$\begin{aligned} K &= \frac{1}{2}(M_1\dot{x}_1^2 + M_2\dot{x}_2^2 + M_3\dot{x}_3^2) = \frac{M_1\dot{x}_1 + M_2\dot{x}_2 + M_3\dot{x}_3}{2(M_1 + M_2 + M_3)} \\ &+ \frac{M_1(M_2 + M_3)(\dot{x}_2 - \dot{x}_1)^2}{2(M_1 + M_2 + M_3)} + \frac{M_3(M_1 + M_2)(\dot{x}_3 - \dot{x}_2)^2}{2(M_1 + M_2 + M_3)} \\ &+ \frac{M_1M_3(\dot{x}_3 - \dot{x}_1)(\dot{x}_2 - \dot{x}_1)}{M_1 + M_2 + M_3} \end{aligned} \quad (19)$$

\* The vibrational states are considered as "harmonic."

<sup>12</sup> Cross and Vleck, *J. Chemical Physics*, 1933, 1, 350.

which gives, if one omits the first term, assuming that the centre of mass is at rest :

$$K = \frac{M_3(M_1 + M_2)}{2(M_1 + M_2 + M_3)}\dot{\eta}^2 + \frac{M_1(M_2 + M_3)}{2(M_1 + M_2 + M_3)}\dot{\xi}^2 + \frac{M_1M_2\xi\dot{\eta}}{M_1 + M_2 + M_3} \\ = \mu_1\dot{\xi}^2 + \frac{1}{2}\mu_2\dot{\eta}^2 + \mu\xi\dot{\eta} \quad (20)$$

If the last term were not present, the motion of the ball could be described in rectangular co-ordinates.

The equations of motion are hence  $\frac{d}{dt} \cdot \frac{\partial K}{\partial \xi} = - \frac{\partial V}{\partial \xi}$ , etc.

$$\mu_1\ddot{\xi} + \mu\ddot{\eta} = -2p\xi \quad (21) \\ \mu\xi + \mu_2\ddot{\eta} = +2q\eta$$

Assuming

$$\xi = a^2 \cos 2\pi\nu t, \quad \eta = b^2 \cos 2\pi\nu t$$

we obtain :

$$4\pi^2\nu^2 = \frac{p\mu_2 - q\mu_1 \pm \sqrt{(q\mu_1 - p\mu_2)^2 + 4qp(\mu_1\mu_2 - \mu^2)}}{(\mu_1\mu_2 - \mu^2)} \quad (22)$$

One of the two values of  $4\pi^2\nu^2$  is positive, corresponding to the stable vibration  $\nu_s$ , the other negative corresponding to the unstable vibration  $\nu_u$ .

The values for  $p$  and  $q$  can be estimated from the Fig. 2 which shows the two cross-sections of the saddle,  $p = 3 \cdot 10^8$  cal./mole  $\text{\AA}^2$ ,  $q = 4 \cdot 10^8$  cal./mole  $\text{\AA}^2$ . For the reaction (1) this value of  $p$  and  $q$  gives  $\frac{1}{2}h\nu_s = 5300$  cal./mole,  $\frac{1}{2}h\nu_u = 1840$  cal./mole. There is no objection on theoretical grounds against the first figure. A glance at Fig. 2b shows, however, that a negative zero point energy of 1840 cal. is not possible in this case, since the energy—distance curve of Fig. 2 does not continue to be even nearly parabolic thus far. We have arbitrarily decreased  $\frac{1}{2}h\nu_u$  to 1000 cal./mole in the low temperature region. It should be mentioned that it is not possible to justify this procedure at present, but it hardly affects our results. Eckart<sup>13</sup> has shown how to calculate the non-classical penetration of potential barriers of rather different shapes and Bell<sup>14</sup> has

used his results for the reaction  $\text{H} + \text{H}_2$ . It must be mentioned, however, that Eckart's results apply to a one-dimensional problem only and the fact that Bell omitted to take the zero point energy  $\frac{1}{2}h\nu_u$  of the perpendicular vibration into account

FIG. 2.

<sup>13</sup> Eckart, *Physic. Rev.*, 1930, **35**, 1303.

<sup>14</sup> Bell, *Proc. Roy. Soc.*, 1933, **139A**, 466.

invalidates his results to some extent. On the other hand the method for many dimensional barriers<sup>8</sup> is applicable only if the  $\frac{h\nu}{kT}$  are not great, i.e., in the high temperature region only. Here (17) has been used consequently, with  $\frac{1}{2}h\nu_d = 1840$  cal./mole. Since the formula, though not sensitive for  $h\nu_d$ , the tunnel effect being always comparatively small, is rather sensitive for  $\frac{1}{2}h\nu_s$ , the latter *has been determined from the measurements* (cf. section 4) and  $p$  calculated backwards. From this new  $p$  the  $\frac{1}{2}h\nu_s$  were obtained for the other reactions since the ratios of  $h\nu_s$  and  $h\nu_d$  are practically independent of the value of  $p$ . These ratios, as obtained with aid of formula (22), are listed in Table II.

While the displacements are in the direction of the internuclear line for the vibrations  $\nu_s$  and  $\nu_d$ , they are perpendicular to this in the deformation vibration  $\nu_d$ . We shall denote these displacements by  $y_1, y_2, y_3$  for the atoms 1, 2 and 3, the condition that the centre of gravity is at rest and  $y = 0$ , is then

$$M_1 y_1 + M_2 y_2 + M_3 y_3 = 0 \quad . \quad . \quad (23)$$

We can put down the condition, furthermore, that the molecule has no angular momentum around the middle atom (in virtue of the previous equation this holds, then around any point):

$$M_1 y_1 \cdot 1.25 - M_3 y_3 \cdot 0.85 = 0 \quad . \quad . \quad (24)$$

The deformation angle  $\delta$  is

$$\delta = \frac{y_1 - y_2}{1.25} + \frac{y_3 - y_2}{0.85}$$

and the potential energy  $s\delta^2$ . The equations of motion are:

$$M_1 \ddot{y}_1 = - \frac{\partial V}{\partial y_1} = - \frac{2s\delta}{1.25}$$

and similar equations for  $y_2$  and  $y_3$ , which are automatically fulfilled, however, if we assume (23) and (24) from the beginning. These equations allow us to express  $y_3$  and  $y_2$  by  $y_1$  and thus  $\delta$  by  $y_1$  alone. The equation of motion one obtains thus, is:

$$\ddot{y}_1 = \alpha y_1 \quad . \quad . \quad . \quad (25a)$$

$$\alpha = 2s \cdot \left[ \frac{1}{1.25^2 M_1} + \frac{1}{0.85^2 M_3} + \left( \frac{1}{1.25} + \frac{1}{0.85} \right)^2 \frac{1}{M_2} \right] \quad . \quad (25b)$$

the deformation frequency is consequently

$$\nu_d = \frac{1}{2\pi} \sqrt{\alpha} \quad . \quad . \quad . \quad (26)$$

The constant  $s$  should have, according to the calculated energy surface, the value 9000 cal./mole. This gives  $h\nu_d = 2150$  cal./mole for reaction (1). It should be mentioned, however, that the value of  $s$  is rather sensitive to small changes of the constants from which the energy surface is derived, and not too much stress should be laid on this value of  $h\nu_d$ .

The ratios of  $\nu_d$  for the different complexes are listed also in Table II. in which the symbol means (e.g., D—DH) the activated complex of reaction (4) in which the H is nearer to the central D atom than the other D.

This completes the calculation of the frequencies. The ratio of the frequencies for reactions (1) and (2) is always  $\sqrt{2}$ , independent of the actual model assumed.

TABLE II.

Symbol.	Relative.			$I_c$ .
	$\nu_s$ .	$\nu_t$ .	$\nu_d$ .	
H—HH . . .	5.4	1.77	2.43	$3.71 \times 10^{-40}$
D—DD . . .	3.8	1.25	1.72	$7.42 \times 10^{-40}$
D—HH . . .	5.4	1.42	2.37	$5.25 \times 10^{-40}$
DH—H . . .	4.6	1.38	2.39	$4.90 \times 10^{-40}$
H—DD . . .	3.8	1.60	1.81	$4.90 \times 10^{-40}$
HD—D . . .	4.7	1.30	1.91	$5.52 \times 10^{-40}$

The moment of inertia of the complex  $I_c$  which is necessary to calculate the velocity constant according to formula (17) can also be readily obtained from the energy surface. As already mentioned the distances of the end atoms from the central atom are 0.85 Å. and 1.25 Å. In the symmetric case there is only one momentum of inertia, in the asymmetric ones, the momentum of inertia of the complex is different in the two activation points.

If  $x$  is the distance of the centre of gravity from the middle atom, the momentum of inertia is given by

$$I_c = M_1(1.25 - x)^2 + M_2x^2 + M_3(0.85 + x)^2$$

and

$$x = \frac{M_1 1.25 - M_3 0.85}{M_1 + M_2 + M_3} \quad (27)$$

$I_c$  does not depend very much on the dimension of the complex. The moment of inertia of the  $H_2$  molecule is known from spectroscopical data. It is  $0.467 \times 10^{-40}$  g. cm.<sup>2</sup> and is twice as great for  $D_2$ .

#### 4.

In fact the energy surface for reactions 1 to 4 is not known at present with sufficient accuracy, especially not for the calculation of the constants for which (7) is sensitive, i.e.,  $Q$ ,  $\nu_s$  and  $\nu_d$ . Therefore another procedure will be adopted in this section: a part of the experimental data will be used to calculate the constants of the energy surface relevant for these quantities.

First of all we shall compare the reaction rates of (1) and (2) in the high temperature region. This ratio is, according to Table I, 1.65 at 950° abs. and we obtain the following equation:

$$\frac{k_1}{k_2} = 1.95 = 2^{3/2} \frac{\sinh 3.29}{\sinh 2.34} \cdot \left( \frac{\sinh \beta \nu_d / \sqrt{2}}{\sinh \beta \nu_s} \right)^2 \frac{\sinh \beta \nu_s / \sqrt{2}}{\sinh \beta \nu_s} \frac{(1 + \frac{1}{2}(3700\beta)^2)^*}{(1 + \frac{1}{2}(3700\beta)^2)} \quad (28)$$

\* This formula for the ratio of the velocity constants of the two isotopic reactions is essentially the same—if we neglect the tunnel effect—as the usual one, derived from the kinetic expression (16).

The difference in the "over all" activation energy of the two isotopic reactions is at low temperatures  $0.15(h\nu_m - h\nu_s - 2h\nu_d)$ .

[Continuation of footnote on next page.]

if  $\nu_d$  and  $\nu_s$  are the constants of the complex HHH and 3700 cal., according to the calculation on page 715,  $\nu_s$  for HHH. Since  $\beta\nu_d$  is certainly not greater than unity, we can put  $\sinh x = x + \frac{x^3}{6}$  and thus we obtain finally :

$$\frac{\sinh \beta\nu_s/\sqrt{2}}{\sinh \beta\nu_s} = 0.54$$

which gives  $\beta\nu_s = 1.9$  and  $h\nu_s = 7200$  cal./mole.

In order to calculate the energy of the activation point  $Q$  we shall use the experimental figures for the temperature dependence of  $k_1$ . From the figures of the Table I. yields

$$Tw_{\text{exp.}} = T \frac{d \ln k_1}{dT} = 3.4 \text{ to } 3.5 \quad . \quad . \quad . \quad (29)$$

whereas theoretically we obtain for the expression  $T \frac{d \ln k_1}{dT}$  from equation (17)

$$T \frac{d \ln k_1}{dT} = -\frac{1}{2} + \frac{Q}{RT} - \beta\nu_m \coth \beta\nu_m + 2\beta\nu_d \coth \beta\nu_d + \beta\nu_s \coth \beta\nu_s - \frac{\beta^2\nu_s^2}{3(1 + \frac{1}{6}\beta^2\nu_s^2)} \quad (30)$$

Inserting the values for  $\nu_m$ ,  $\nu_s$  and  $\nu_d$  and putting  $2\beta\nu_d \coth \beta\nu_d$  approximately \* 2.20 we obtain by comparison with the experimental value for

$$Q/RT = 3.4 \text{ and } Q = 6400 \text{ cal.}$$

According to this calculation the energy of the activation point is rather low and is not in good agreement with the calculated value<sup>9</sup> which is 20,000 cal. However the first approximation calculations of chemical bonds are generally uncertain by this amount. The remaining unknown frequency  $\nu_d$  will be determined from the absolute value of the reaction rate of (1) at 950° abs.

$$1.85 \times 10^9 = \frac{2.4 \times 10^{11}}{30.8} e^{-\frac{6400}{RT}} \cdot \frac{\sinh 3.29}{\sinh 1.90} \cdot \frac{1.16}{(\sinh \beta\nu_d)^2} \quad (31)$$

This equation solved yields  $\beta\nu_d = 0.74$  and thus  $h\nu_d = 2800$  cal./mole.

In the ratio of the two velocity constants the factor

$$= \frac{\sinh \beta\nu_m}{\sinh \beta\nu_m/\sqrt{2}} \cdot \frac{\sinh \beta\nu_s/\sqrt{2}}{\sinh \beta\nu_s} \cdot \left( \frac{\sinh \beta\nu_d/\sqrt{2}}{\sinh \beta\nu_d} \right)^2$$

tends at low temperatures to  $e^{(h\nu_m - h\nu_s - 2h\nu_d) \left(1 - \frac{1}{\sqrt{2}}\right) \frac{1}{2RT}}$ .

The factor  $2^{3/2}$  in the ratio  $\frac{k_1}{k_2}$  is partially compensated by the term

$$\left( \frac{\sinh \beta\nu_s/\sqrt{2}}{\sinh \beta\nu_s} \right)^2$$

and becomes (at high temperatures)  $\sqrt{2}$ . In the kinetic formula this  $\sqrt{2}$  arises from the lower number of collisions in the heavier isotope.

\* For small  $\beta\nu_d$ ,  $2\beta\nu_d \coth \beta\nu_d \approx 2$ .

## 5.

In this section we shall compare the theoretically calculated values for  $k_3$  and  $k_4$  with the experiments and calculate the reaction rates of (1) and (2) at low temperatures. In the case of  $H + H_2 \rightleftharpoons H_3 + H$  the theoretical figures can be checked also by the experiments.

$k_3$  and  $k_4$  can be estimated on basis of the values of  $Q$ ,  $\nu_3$ ,  $\nu_4$  and  $\nu_5$  obtained in the preceding sections with aid of the Table II. In these cases, however, the molecular constants of the complexes in the two activation points are not equal, and consequently also the number of passages over the two saddles will be different. The number of passages over the two saddles of the reaction (3) is given by

$$(D - HH) : n_3' = 3.6 \times 10^8 \left( \frac{4}{2.2} \right)^{3/2} 11.25 \frac{\sinh 12400\beta(1 + \frac{1}{2}2960^2\beta^2)}{(\sinh 2730\beta)^2 \sinh 7200\beta} \quad (32)$$

$$(DH - H) : n_3'' = 3.6 \times 10^8 \left( \frac{4}{2.2} \right)^{3/2} 10.50 \frac{\sinh 12400\beta(1 + \frac{1}{2}2880^2\beta^2)}{(\sinh 2750\beta)^2 \sinh 6140\beta} \quad (33)$$

which yields for  $n_3' = 2.95 \times 10^9 \frac{\text{mole}}{\text{litre sec.}}$

and for

$$n_3'' = 3.5 \times 10^9 \frac{\text{mole}}{\text{litre sec.}} \text{ at } 950^\circ \text{ abs.}$$

Analogous formula for the reaction  $H + D_2$  gives for the saddle (H - DD)

$$n_4' = 2.0 \times 10^9 \frac{\text{mole}}{\text{litre sec.}},$$

and for the saddle (HD - D)

$$n_4'' = 1.7 \times 10^9 \frac{\text{mole}}{\text{litre sec.}}$$

at the same temperature.

The number of atomic interchanges which in the symmetric cases was calculated with  $\gamma = \frac{1}{2}$  from the number of passages over one of the saddles, in the case of the reactions (3) and (4) can only be estimated. Since for  $n' = n''$   $\gamma = \frac{1}{2}$ , and for the other limiting case if  $n' > n''$  with  $\gamma = 1$ ,  $k = n''$ , we shall put in both cases  $\gamma = \frac{2}{3}$ , and thus  $k_3$  and  $k_4$  become

$$k_3 = 2.2 \times 10^9 \frac{\text{mole}}{\text{litre sec.}}$$

$$k_4 = 1.27 \times 10^9 \frac{\text{mole}}{\text{litre sec.}}$$

In order to compare these theoretical values for  $k_3$  and  $k_4$  with the experiments we have to insert them into the formula (15) of section 1. The right side of the formula yields  $1.65 \times 10^9$  in agreement with the experimental value  $1.4 \times 10^9$ . The agreement must be considered quite good, especially since the right side of the formula (15) is proportional to  $\gamma$ , which was chosen rather arbitrarily  $\frac{2}{3}$ . Unfortunately, lack of more experimental and theoretical data about the reactions (3) and (4) makes it impossible for us at present further to check formula (15) for a wide range of  $H_2$  and  $D_2$  concentrations, and also for different temperatures.

It is remarkable that the velocity of reaction (3) is the fastest among all elementary reactions of hydrogen. This is caused by the comparatively low zero point energy of the activated complexes  $D-HH$  and  $DH-H$ . This was predicted by Polanyi<sup>15</sup> on qualitative considerations.

In Fig. 3 the energy diagrams for all the reactions (1 to 4) are sketched.

In the *initial state* the zero point energy difference of H and D is neglected (the zero point energy difference of H and D is 84 cal., H having with this amount greater ionisation energy), in the *activated state* only the *positive part of the zero point energy* is taken into account. Qualitatively the energy levels of the complexes are in the same order like those which, in the paper of Farkas and Farkas were calculated on basis of rather crude assumptions about the force constants of the activated complexes. The main difference in the absolute values of the zero point energies arises from the inclusion of the deformation frequencies which were neglected in *cf.* 2.

Much less satisfactory is the agreement between the theoretically calculated rates for the reaction (1) and the experimental figures at low temperatures, as given in Table I. For the reaction (2) thus far no experimental data are known at low temperatures.\*

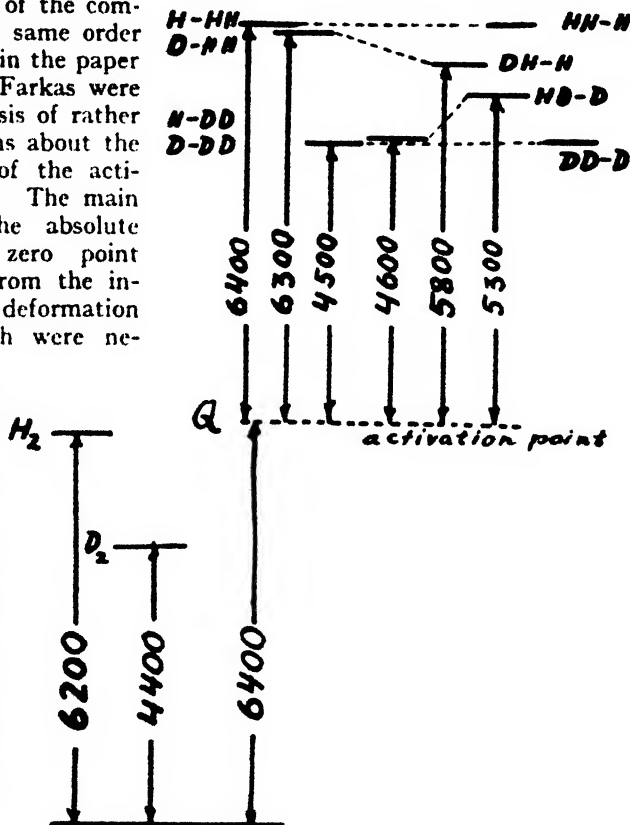

FIG. 3.

With the constants,  $Q$ ,  $\nu_a$ ,  $\nu_d$  obtained in section 4 and  $\nu_t$  which was derived from the rough energy surface, the calculation of the rates of the reaction (1) is as follows:

The tunnel effect in this region as mentioned on page 715 is sufficiently accurately given by  $(1 + 1/6(2000\beta)^2)$  which factor has at  $T = 283^\circ$  abs. the value 1.52 and, at  $T = 373^\circ$ , 1.30. At this temperature region  $\sinh x$  can be replaced by  $\frac{1}{2}e^x$  and we obtain, inserting the numerical values into (17),

<sup>15</sup> Polanyi, *Nature*, 1934, 133, 26.

\* According to the theoretical formula (17) the ratio of  $k_1/k_2$  should at room temperature be 3.1.

$$5.7 \times 10^{10} \times 1.52e^{-\frac{6600}{283 RT}} = 6.9 \times 10^5 \frac{\text{mole}}{\text{litre sec.}},$$

$$5.0 \times 10^{10} \times 1.30e^{-\frac{6600}{373 RT}} = 8.8 \times 10^6 \frac{\text{mole}}{\text{litre sec.}},$$

instead of the experimental figures of  $1.3 \times 10^5 \frac{\text{mole}}{\text{litre sec.}}$  and  $3.1 \times 10^6 \frac{\text{mole}}{\text{litre sec.}}$  at the corresponding temperatures.

The 6600 Cal. which appears in the exponential factor is the "over all" activation energy at low temperatures. This energy  $W$  is in this region

$$W = Q - \frac{1}{2}h\nu_m + h\nu_d + \frac{1}{2}h\nu_s.$$

Theoretically,  $k_1$  is thus given by :

$$k_1 = 6.06 \times 10^{20} \times \left( \frac{M_a + M_m}{M_a M_m} \right)^{3/2} \frac{I_c}{I_m} \frac{h^2}{\sqrt{2\pi k}} T^{-1/2} e^{-\frac{W}{RT}} \left( 1 - \frac{1}{6} \left( \frac{500}{T} \right)^2 \right)^* \quad (34)$$

$T$  enters into this formula, besides the exponential factor essentially in the  $-\frac{1}{2}$  power, in contrast to the kinetic formula, and also to the theoretical temperature dependence at high temperatures.

It is at present impossible to tell whether this discrepancy is caused by some errors in the experiments or by the imperfection of the theory. It must be emphasised, however, that it is impossible to fit both the low and the high temperature measurement on the reaction rate of (1) to the theoretical calculations by alteration of the constants  $\nu_s$ ,  $Q$ ,  $\nu_d$  of section 4.

If one uses the low temperature measurements, instead of the temperature dependence of  $k_1$  at high temperatures, to determine the vibrational frequencies, one obtains the following set of values:  $h\nu_s = 10600$  cal./mole,  $h\nu_d = 1500$  cal./mole and the activation energy becomes 7800 cal./mole. With these constants one can fit all measurements, except, however, the temperature dependence of  $k_1$  and  $k_2$  in the high temperature region.

Possibly the calculation of  $Q$  from the temperature dependence of  $k_1$  at high temperatures according to equation (30) is affected with the greatest inaccuracy. The temperature dependence of  $k_1$  is namely derived from the data about the thermal conversion of  $p\text{-H}_2 \rightarrow o\text{-H}_2$ . The velocity of this reaction varies very much, since the thermal H atom concentration is enormously increased with rising temperature, and thus the directly measured figures on the temperature dependence of the reaction  $p\text{-H}_2 \rightarrow o\text{-H}_2$  show a more than ten times higher temperature coefficient than that of  $k_1$  itself. In  $k_1$ , for instance, the increase of the thermal H atom concentration has been taken already into account. In this connection it should be mentioned that the experimental figure for  $\frac{T \ln k_2}{dT}$  is practically the same as for reaction (1), namely 3.5, whereas

\* By dividing this formula by the kinetic formula (16) (if we neglect the tunnel effect) we obtain for the steric factor the complicated expression

$$S = \frac{M_a + M_m}{M_a M_m} \times \frac{I_c}{I_m} \times \frac{h^2}{(d_s + d_m)^2 2\pi k T}$$

Hence  $S$  is, in the low temperature region, proportional to  $T^{-1}$ .

according to the formula (30) the theoretical value with the respective values for the molecular-constants of the complex DDD yields 4.12. This discrepancy may be due to the state of affairs just mentioned, which holds also for reaction (2). A small uncertainty in the larger temperature coefficients of the thermal *ortho-para*-conversions causes a comparatively large uncertainty in the temperature dependence of reactions (1) and (2).

If we assume that the measurements at high temperatures on the reactions (1) and (2) are fairly correct, the discrepancy at low temperature between the experimental data and the theoretical rate must be ascribed, as already mentioned, either to errors in the experiments or to some imperfection of the theoretical treatment. It is planned to revise the experimental data in a wide temperature range for both reactions, since it seems very important to decide whether the present theory of reaction velocities, as developed recently, is correct or not.

### Summary.

The velocity constants of the elementary reactions of hydrogen and deuterium

are calculated on basis of the formula

$$k = \gamma \frac{1}{2} \times \left( \frac{M_a + M_m}{M_a M_m} \right)^{1/2} \frac{I_c}{I_m} \times \left( \frac{h}{2\pi} \right)^2 \sqrt{\frac{2\pi}{hT}} \times e^{-Q/RT} \frac{N_L}{1000} \\ \times \frac{\sinh \beta \nu_m}{(\sinh \beta \nu_d)^2 \sinh \beta \nu_s} \cdot (1 + \frac{1}{2} \beta^2 \nu_s^2)$$

which was derived by Pelzer and Wigner and Wigner for this type of reaction. The constants  $\nu_m$  and  $I_m$  of the molecule are known from spectroscopic data. The molecular constants  $I_c$ ,  $\nu_s$ ,  $\nu_d$  for the different complexes involved in reactions (1 to 4) are partly computed by the energy surface of these reactions and partly obtained by comparison of one part of the experimental data with the theory. The remaining experimental data on reactions (1 to 4) are then compared with the calculated velocity constants.

# THE PHOTO-OXIDATION OF METHYLENE IODIDE.

BY R. A. GREGORY AND D. W. G. STYLE.

*Received 31st January, 1936.*

## PART I.

The photo-oxidation of methyl and ethyl iodides has already been investigated and the products obtained interpreted in terms of reactions between the methyl and ethyl radicals and molecular oxygen.<sup>1</sup>

The importance of these radicals in the oxidation of organic compounds is, however, probably secondary to that of the methylene radical.<sup>2</sup> Kassel,<sup>3</sup> as a result of his study of the pyrolysis of methane, suggested that this radical was chemically rather inert. More recent work, however, has thrown considerable doubt on the reality of the inertness of methylene and the part played by it in methane pyrolysis.<sup>4</sup> The investigation of reactions in which there are good grounds for believing that methylene is formed is, therefore, likely to be of considerable value. Norrish<sup>5</sup> has demonstrated the probable formation of methylene by the photo-decomposition of diazomethane, and the photo-dissociation of gaseous methylene iodide might also be expected to give rise to this radical.

Methylene iodide was chosen for the present work on account of its far greater stability. Parallel experiments with diazomethane were also commenced but discontinued after a number of explosions had been experienced.

### Materials.

Commercial methylene iodide was treated with thiosulphate to remove iodine, washed with water and, after drying with calcium chloride, was distilled *in vacuo*.

Oxygen from a cylinder was passed through a liquid air trap and used without further purification.

### Apparatus.

Preliminary experiments to discover the nature of the products and the best conditions were carried out in the simplest possible manner. Oxygen stored in an aspirator was sucked by a "Hyvac" pump through a train consisting of a drying tube, capillary, bubbler filled with methylene iodide, a cylindrical silica reaction cell, a second capillary and a liquid air trap. The capillaries were chosen so as to give a pressure of a few cms. of Hg in the cell, which was illuminated with the full light of a mercury arc.

The results obtained indicated the probable formation of gaseous products. The low vapour pressure of methylene iodide (about 1 mm. Hg at room temperature) was not favourable to the use of a static system and a closed circulating system was consequently adopted.

The apparatus is shown diagrammatically in Fig. 1.

Two thermostats were employed, one of which contained only the methylene iodide saturator A, consisting of 40 cms. of 2 cm. diameter tubing placed horizontally and about half filled with methylene iodide. From one end of the saturator a tube led directly to the reaction cell, B, which was fixed in front of a quartz window in the second thermostat. The other end of the reaction cell was connected with the traps C, D, E, the manometer F, the flow meter G, and the mercury diffusion pump H, which worked satisfactorily up to pressures of 20 mm. Hg.

Following the pump came a half-litre bulb I, which brought the total volume up to a suitable value and being placed in the second thermostat, helped to nullify the effects of temperature changes on the unthermostated portions of the apparatus. Finally, the bulb was connected through a trap K, to remove mercury vapour, with the other end of the saturator.

Leads were taken to a Hyvac pump and to a Toepler pump, which extracted specimens of the gas for analysis in a Bone and Wheeler apparatus. The manometers F and G were filled with butyl phthalate. Exposed tubing with which methylene iodide came in contact was heated above the condensation temperature electrically.

The effective volume of the apparatus under working conditions was determined by admitting oxygen at atmospheric pressure from the calibrated volume M to the apparatus and measuring the pressure increase on F. The total volume was about 1200 c.c. and the usual rate of circulation about 24 litres per hour.

The light source was an atmospheric quartz mercury arc burning at 2.2 amperes from a regulated 110 volt circuit. Especially in the later experiments the light was rendered approximately parallel with a quartz lens and for some series a 5 mm. layer of potassium chromate (0.5 gm. per litre) was used as a filter.

Two reaction cells were used. The first was a cylindrical bulb 4.5 cm. diameter and volume 150 c.c. with inlet and outlet tubes at opposite ends. It was placed broad-side on to the light beam. The second cell was also cylindrical but fitted with plane parallel end plates. It was 10 cm. long and of volume 220 c.c. Its disposition is shown in Fig. 1. The first cell was attached to the apparatus by ground joints sealed with "Apeizon" wax, the second by graded silica-soda glass seals.

### Procedure.

In order to obtain enough of the products for an accurate analysis, each experiment was continued for about three hours or, when low intensities were used, six hours.

A mixture of ice and salt was placed around the trap C and liquid air around the others. Oxygen was then admitted to the desired pressure, and the heating of the circulating pump adjusted to give the correct rate

FIG. 1.

of flow. As soon as steady conditions had been obtained, the insolation was commenced.

At the conclusion of the insolation, the traps C and D were isolated and evacuated in order that the entire condensate could be distilled into the trap C, which was made in the form of a U-tube in order to ensure that all of the condensate was removed for analysis.

Meanwhile a portion of the gas was pumped off and analysed for carbon monoxide and hydrogen, which were the only gaseous products which could be detected.

In addition to iodine, the following were shown to be present in the condensate by means of the tests given.

*Formaldehyde*.—(1) Formation of polymer m.p.  $172^{\circ}$ , which decomposes to give smell of formaldehyde.

(2) Derivative with 3 : 5 dinitro-phenylhydrazine m.p.  $155^{\circ}$ .

*Formic Acid*.—(1) Characteristic test with  $\text{HgO}$ .

(2) Acidity to methyl orange.

*Ethylene Glycol*.—(1) Formation of dibenzoate m.p.  $71.5^{\circ}$ .

(2) Formation of 2:4 dinitrobenzoate which exploded at about the same temperature as a known specimen. Instead of ethylene glycol the products may be ethylene oxide and water. The concentrations available were insufficient to enable this rather minor point to be settled. There was no evidence for any other substances and in particular methyl or ethyl alcohols, which were especially looked for.

For the quantitative analysis of the condensate the following procedure, which was tested out with known mixtures, was adopted :

Free iodine was first titrated with  $N/10$  thiosulphate, a more dilute solution being found inadvisable as the accuracy of the formaldehyde estimation was reduced if the volume of the aqueous layer was too large. The formic acid was then titrated with  $N/50$  NaOH using methyl orange as indicator, and the formaldehyde then determined by the well-known hydroxylamine method.

For ethylene glycol no satisfactory analytical method could be found,

and recourse had to be had to "element balances." The carbon, hydrogen and oxygen unaccounted for as  $\text{HCOOH}$ ,  $\text{HCHO}$ ,  $\text{CO}$  or  $\text{H}_2$  in a few typical cases is shown in Table I. The data from which they have been calculated are given in Table II.

Although rather irregular, it is clear that the ratios of C : H : O average closely to 1 : 3 : 1, the empirical formula of glycol. It is therefore very improbable that any other substance is formed in appreciable amount.

TABLE I.—MOLS.  $\times 10^{-4}$  PER HOUR  
UNACCOUNTED FOR.

No.	C	H.	O.	$2(\text{CO} - \text{H}_2)$ .
2	0.409	1.240	0.431	0.422

24	0.897	2.580	1.014	0.786
26	0.878	2.638	0.742	0.882

It will be further observed that the last column of Table I. which gives twice the difference between the mols. of carbon monoxide and hydrogen formed is always very near to the unaccounted carbon and oxygen. We have accordingly assumed that carbon monoxide and glycol are formed in the reaction in equimolecular proportions. There then remains unexplained a small quantity (about 10 per cent. of the total) of carbon monoxide and an equivalent quantity of hydrogen. This is almost certainly due to photo dissociation of formaldehyde.

The amount of glycol can therefore be calculated from the difference between the carbon monoxide and hydrogen, or from the carbon or oxygen balances.

### Results.

Complete analyses were in general carried out for each run.

The experimental results are given in Table II. The runs up to number 26 were obtained with the "bulb" cell illuminated with the full mercury arc light. For the subsequent runs the cylindrical cell with plane end-plates was used. The light was filtered through potassium chromate solution for runs 37 to 59, but no filter was used for the last runs.

When the oxygen was replaced by hydrogen the amount of iodine formed was barely detectable.

In addition to the results of Table II., a few runs were carried out with oxygen at atmospheric pressure in which the yield of iodine was approximately what would be expected from an extrapolation of the results obtained at the lower pressures. These are not included, since some formaldehyde polymer tended to form in the cell, and their accuracy is therefore suspect.

During the determination of the quantum yield, however, when the intensities were very much lower, no trace of polymer was formed, although the total pressure was also atmospheric.

The pressure drop across the flowmeter capillary was maintained throughout at 25 mm. of butyl phthalate, and in order to interpret the results, it was necessary to convert this pressure difference to the equivalent rate of flow at the various pressures used. The calibration was effected during runs 37 to 59 by weighing the condensate collected in the traps.

If  $p_m$  is the pressure recorded by the manometer F (Fig. 1),  $T_m$  its temperature,  $T_s$  the reaction cell temperature,  $p_s$  the vapour pressure of methylene iodide at the saturator temperature,  $V_s$  the volume rate of flow of oxygen through the cell,  $V_m$  that through the flowmeter, and  $W$  is the weight of products collected in unit time, we have :

$$\frac{p_m V_m}{RT_m} = \frac{(p_m - p_s) V_s}{RT_s} = \frac{p_m - p_s}{p_s} \cdot \frac{W}{268}.$$

The flowmeter was unthermostated but the room temperature was constant to within 3° C.

In the above it is assumed that there is no pressure drop between the cell and the manometer. This was tested by adding a second manometer temporarily to the outlet tube of the cell. No appreciable difference in pressure appeared until the total pressure was reduced below 5 mm. At 4 mm. of mercury the difference was 0.2 mm. Hg.

The error introduced by the reaction products is negligible since at the most only 8 per cent. of the methylene iodide reacted and the weight of the oxygen absorbed is partially offset by the formation of carbon monoxide.

Direct diffusion of methylene iodide from the saturator to the traps does not occur under the conditions used, since with the saturator at 35° C. ( $p_s = 2.52$  mm.) and a time of 3 hours no detectable amount of methylene iodide collected in the trap until the total pressure was reduced below 4 mm. Hg.

Variation of the intensity produced rather less than a proportional change in the rate of formation of iodine. A screen transmitting 16.8 per cent. of the incident intensity reduced the rate of iodine formation to 24.1 per cent., 22.1 per cent. and 19.5 per cent. when the oxygen pressures were respectively 4.0, 6.1 and 20.0 mm. Hg.

Increasing the rate of flow causes an increase in the rate of iodine formation.

The only data discoverable in the literature <sup>6</sup> for the vapour pressure of methylene iodide are two boiling-points, one for atmospheric pressure, 180°

[illegible]

with decomposition, and the other 88° at 39 mm. Hg. It was, therefore, necessary to determine the course of the vapour pressure-temperature curve over the range covered by the kinetic measurements.

#### Vapour Pressure.

Methylene iodide was placed in a flat bulb about 6 cm. in diameter connected with a sensitive "spoon" gauge and evacuated with a Hyvac pump. All parts of the apparatus with which methylene iodide vapour came in contact were immersed in a thermostat. The outside of the spoon gauge was balanced by admission of air, the pressure being measured by a butyl phthalate manometer which was continuously evacuated on one side. The data in Table III. can be represented by the equation :

$$\log_{10} p = 8.566 - \frac{2520}{T}$$

with a maximum error of 8 per cent.

TABLE III.—VAPOUR PRESSURE DATA.

				55.0	7.53

#### Quantum Yield.

The quantum yield with respect to iodine was determined for light of mean wavelength about 3100 Å. isolated from the mercury arc spectrum by means of a large quartz monochromator. The reaction cell was the same as that used in runs 37 onwards. For the sake of convenience it was decided to use oxygen at atmospheric pressure saturated with methylene iodide at 21° which was about 1 degree lower than the temperature at which the cellar in which this determination was carried out, could be readily maintained.

The light from the exit slit of the monochromator was rendered approximately parallel by a quartz lens before passing through the cell and finally focussed by a second lens onto a Moll surface thermopile. The E.M.F. generated in the thermopile was measured with a Cambridge vernier potentiometer in conjunction with a Kipp and Zonen Zernicke Zc galvanometer. The thermopile was calibrated against a standard lamp supplied by the U.S. Bureau of Standards. Readings of the incident and transmitted intensities were taken at hourly intervals, by first noting the E.M.F. while the gas stream was flowing and then closing a tap between the saturator and the reaction cell and, after evacuating the cell, again taking the potentiometer reading.

The duration of each run was six hours. The readings obtained had to be corrected for the reflection losses at the crystal quartz plate covering the thermopile, the second quartz lens and the back plate of the cell. Those at the plate and lens were calculated as for two plates and that of the back plate of the cell was taken as the square root of the total loss in the cell. Since the total light lost in passing through the cell was rather greater than that calculated for two plates, the cell was reversed for half of the determinations, without, however, causing any detectable change in the observed quantum yield. In order to avoid as far as possible complications due to back reflections from the large number of surfaces in the light path, all

apparatus was tilted a few degrees from the perpendicular to the optical axis.

The values of the quantum yield obtained were 1.47, 1.46, 1.44, 1.45, 1.43, 1.44, giving as the mean 1.45.

According to Henrici<sup>7</sup> the maximum of the extinction coefficient lies at about 3000 Å. No further data was discoverable in the literature. The absorption spectrum of gaseous methylene iodide was accordingly determined photographically using a Spekker photometer.

FIG. 2.

The logarithms of the decadic molecular extinction coefficients are plotted against the wavelength in Fig. 2, which also includes one value for 313 mμ obtained by the thermopile-galvanometer method.

### Discussion.

There exist two alternatives for the primary photo process:—

By analogy with other somewhat similar cases we may, however, expect that the remaining iodine atom in  $\text{CH}_2\text{I}$  is very weakly bound so that even with (1a) free methylene may in fact be formed very shortly after the light absorption. The succeeding reactions will be essentially the same with both processes and in the absence of definite data (1b) will be assumed to occur.

Succeeding (1b) the following series of reactions which is the simplest of those we have tried and provides the most satisfactory mechanism, is assumed to occur:—

or

<sup>7</sup> A. Henrici, *Z. Physik*, 1932, 77, 35.

As will be shown in a later paper, the reacting system possesses strong oxidising powers, which we believe to be due to the two molecules,  $\text{CH}_2\text{O}_2$  and  $(\text{CH}_2\text{O})_2$ , methylene peroxide and ethylene peroxide.

Reaction 7 was introduced only with considerable diffidence. The equivalence of the carbon monoxide and glycol formed is, however, explained by this reaction so satisfactorily, while no other suitable reaction could be found, that there seems no doubt that, granting the validity of the remaining reactions, this reaction is a real one.

The monomolecularity of reactions (4) and (6) will be discussed later.

Reaction between methylene and methylene iodide to produce ethylene and iodine apparently does not occur since no ethylene could be found among the gaseous products when solid  $\text{CO}_2$  was placed around the traps instead of liquid air. The difficulties of detecting a trace of ethylene iodide or ethylidene iodide in the products makes it impossible to decide whether either of these substances is produced.

The gases entering the reaction cell have, during any one run, an almost constant composition deducible from the total pressure recorded by the manometer F, and the temperature of the saturator thermostat. The gases leaving the reaction cell, will shortly after the commencement of the insolation, when steady conditions have been attained, also have a constant composition, which differs from that of the entrant gases, in that the partial pressures of methylene iodide and oxygen are somewhat reduced ( $\text{CH}_2\text{I}_2$ , a maximum of 8 per cent.) and an equivalent amount of the products is present.

Inside the cell itself diffusion and convection will assist in maintaining the composition spacially fairly uniform. As a simplification it will be assumed that the composition throughout the cell equals that of the outflowing gases.

The steady concentration of the short-lived intermediates  $\text{CH}_2$ ,  $\text{CH}_2\text{O}_2$ ,  $(\text{CH}_2\text{O})_2$  should be so low that the amount of them swept away into the traps is negligible compared to that which reacts. On the other hand, the removal of the stable end-products by the gas stream is an important factor determining their concentrations in the cell.

If we represent the concentration in the reaction cell of

by  $\begin{matrix} \text{O}_2, & \text{CH}_2\text{I}_2, & \text{CH}_2, & \text{I}_2 & \text{CH}_2\text{O}_2, & \text{HCHO}, & (\text{CH}_2\text{O})_2, & \text{HCOOH}, & \text{and} & (\text{CH}_2\text{OH})_2 \\ X, & Y, & B, & C, & D, & F, & H, & L, & \text{and} & M \end{matrix}$

respectively, and

let  $E$  be the Einsteins of light absorbed/hour/litre,

$V_0$  be the volume rate of flow through the cell in litres/hour,

and  $\phi$  be the volume of the cell,

the rate of formation of iodine in the cell is given by

$$\frac{dc}{dt} = E + k_5 DY - k_2 BC.$$

The condition for a steady iodine concentration in the cell is that the quantity of iodine formed in unit time equals the quantity removed by the gas stream in the same time;

$$\therefore \phi \frac{dc}{dt} = V_0 C$$

$$\therefore E + k_5 DY - k_2 BC = \frac{V_0 C}{\phi} \quad . \quad . \quad . \quad (8)$$

$D$ ,  $B$  and  $H$  can be evaluated by the usual methods in terms of the

concentrations of the stable substances and on substituting in (8) and simplifying, we get:

$$C = \frac{X}{2d} \left\{ \sqrt{\left(1 + \frac{4\alpha\phi\beta E}{V_0 X}\right)} - 1 \right\}.$$

where

$$\alpha = k_2/k_3 \text{ and } \beta = \frac{2k_5 Y + k_4}{k_5 Y + k_4}$$

The gram mols. of iodine collected in the traps in one hour

$$\begin{aligned} &= V_0 C \\ &= \frac{V_0 X}{2\alpha} \left\{ \sqrt{\left(1 + \frac{4\alpha\phi\beta E}{V_0 X}\right)} - 1 \right\}. \end{aligned}$$

But

$$V_0 X = \frac{V_0(p_m - p_z)}{RT_0} = \frac{V_m p_m}{RT_m}.$$

FIG 3.

$\therefore$  Iodine collected per hour

$$= \frac{V_m p_m}{2RT_m \alpha} \left\{ \sqrt{\left(1 + \frac{4RT_m \alpha \phi \beta E}{V_m p_m}\right)} - 1 \right\}.$$

The best values of  $\alpha$  and  $\phi\beta E$  for each series can be obtained by trial and error and are given in columns 13 and 14 of Table II.

Three typical series of points with the calculated curves fitting them are shown in Fig. 3.

With the exception of the two series of runs 1-7 and 8-14 the values of  $\alpha$  are fairly consistent with one another. The former of the two discordant series requires  $\alpha$  to be many times larger than is found in any subsequent series. The reason remains obscure. No single value of  $\alpha$  will fit the series of runs 8-14, and since the other constants show a

similar unwonted variability, some unsuspected disturbing factor was presumably present, but to a lesser extent, here also. At the conclusion of the series, it was indeed observed that a thin white deposit, volatile when gently heated in vacuum, was present in the cell. This deposit was probably formaldehyde polymer.

To determine the temperature dependence of  $\alpha$  and also to obtain more reliable values of this constant, it was decided to replace the reaction cell previously used by one with plane parallel ends and with inlet and outlet tubes placed in positions more likely to avoid "pockets" unaffected by the gas stream. The partial pressure of  $\text{CH}_2\text{I}_2$  was also reduced to 0.67 mm. Hg (saturation temperature  $15^\circ$ ) and the potassium chromate filter was used.

The energy of activation of  $\alpha$  thus obtained is  $-1920$  Cals. If, as is probable, the reaction between methylene and iodine requires no activation, the activation required for reaction with oxygen is  $+1920$  Cals.

At  $20^\circ$  and  $35^\circ$   $e^{-\frac{1920}{RT}}$  equals 26.5 and 22.6 respectively, while the experimental values of  $\alpha$  at these temperatures are 29.2 and 24.9. The close agreement shows that reactions (1) and (2) are kinetically almost identical. Too great reliance should not perhaps be placed on this energy of activation since, when the methylene iodide partial pressure was raised to 1.82 mm. and the filter removed, the value of  $\alpha$  required at a reaction temperature of  $35^\circ$  was 25.7 which differs rather considerably from the previous value at this temperature of 24.9.

The greatly increased accuracy obtained with the second cell (runs 37-78) seems most easily explicable by the absence of the possibility of the existence of the "backwaters" which was favoured by the design of the first cell.

The remaining four constants can only be evaluated as the two ratios ;

$$k_4/k_5 \text{ and } k_4/k_7.$$

$k_4/k_5$  can be calculated from either of the relations

$$k_4/k_5 = \frac{2Y}{(C/L - 1)} \quad . \quad . \quad . \quad . \quad (9)$$

$$k_4/k_5 = \frac{\bar{X}Y}{\bar{X} - \bar{L}} \quad . \quad . \quad . \quad . \quad (10)$$

the bars denoting that the amounts of the substance formed or used up in unit time are to be used.

The two expressions give within the experimental error the same result, (9) being, however, the more accurate, especially where the amount of reaction is small as in runs 40-62. It is this value which is given in column 11 of Table II.

The quantum yield gives a further value of  $k_4/k_5$ .

In the present work, the quantum yield was determined with so high an oxygen partial pressure that the expression for the iodine collected per hour can be safely simplified to  $\phi\beta E$ . The quantum yield with respect to iodine then becomes equal to

$$\beta = \frac{2Y + k_4/k_5}{Y + k_4/k_5}$$

whence

$$k_4/k_5 = \frac{Y(2 - \beta)}{\beta - 1} = 6.2 \times 10^{-4}.$$

From the results in column 11 of Table II. it can be seen that the same value of  $k_4/k_5$  is not applicable throughout. There is, firstly, a very distinct difference between the values for the two cells, suggesting that the reactions are at least partly heterogeneous. This would explain the great variability of the ratio with the first cell, since the arrangement of its inlet and outlet tubes was not so favourable to a thorough sweeping out of the cell contents by the gas stream. The results obtained with the second cell are far more consistent but there is a definite tendency for the values of  $k_4/k_5$  to be below the average at the lower pressures. This would be accounted for if a reaction between methylene peroxide and adsorbed methylene iodide occurred more readily than the heterogeneous transformation of methylene peroxide into formic acid. From the constancy of the ratio with total pressures between 8 and 20 mm. Hg. reactions 4 and 5 are presumably essentially homogeneous over this pressure range and reaction 4 is truly monomolecular. That the presence of foreign gases slightly accelerates the formation of formic acid is indicated by the considerably higher value of  $k_4/k_5$  deduced from the quantum yield.

The average value of  $k_4/k_5$  at 35° is a little below that at 20°. The difference is, however, not much larger than would be expected from the change in the collision number with temperature, and the excess may well be due to experimental error. If the practical absence of a temperature coefficient for this ratio is taken as meaning that neither reaction requires thermal activation, the minimum mean life of methylene peroxide with respect to its transformation into formic acid corresponding to a collision efficiency of unity for reaction 5 will be of the order of  $5 \times 10^{-7}$  seconds.

The evaluation of  $k_4/k_7$  is most easily effected by means of the relation

$$k_4/k_7 = \frac{\bar{F}(2\bar{F} + \bar{C} - \bar{L})}{2_0V(\bar{C} - \bar{F} - \bar{L})}$$

where  $V_0$  = the volume rate of flow through the reaction cell and  $\bar{C}$ ,  $\bar{L}$ , and  $\bar{F}$  are respectively the gm. mols. of iodine, formic acid and formaldehyde collected in unit time. The values are given in Table II, column 12.

Apart from the absolute value ( $k_4/k_7$  is about twenty times smaller than  $k_4/k_5$ ) there is a surprising similarity between the two ratios.  $k_4/k_7$  is also larger with the first cell than with the second and shows too the same tendency to be below its average value at the lower total pressures. The decomposition of ethylene peroxide is therefore also over most of the pressure range investigated a true homogeneous monomolecular reaction. Unfortunately no values of  $k_4/k_7$  at high pressures could be obtained so that it is not possible to say whether the stability of this peroxide is also reduced by collision with other molecules as is apparently that of methylene peroxide. The decrease in the ratio at low pressures suggests that the surface of the cell favours reaction of the peroxide with formaldehyde rather than its decomposition.

Similar assumptions to those made with  $k_4/k_5$  give ethylene peroxide a minimum mean life of the order of  $10^{-6}$  seconds.

In order to obtain a value of  $k_4/k_5$  from the quantum yield it was assumed that the efficiency of the primary process (I.) was unity. The quantum yield is not however very sensitive to changes in  $k_4/k_5$  and if the efficiency were actually 0.88 instead of unity,  $k_4/k_5$  as calculated from the quantum yield would be in agreement with the other values.

The reaction is now being investigated at higher pressures in order to settle this point.

### Summary.

The products of the photo oxidation of methylene iodide have been studied and a mechanism accounting quantitatively for the products is proposed.

The intermediate formation of  $\text{CH}_2$ ,  $\text{CH}_2\text{O}$ , and  $(\text{CH}_2\text{O})_2$  is assumed. The minimum value of the activation energy of the reaction of methylene with oxygen is 1920 Cals.

The peroxidic substances  $\text{CH}_2\text{O}$ , and  $(\text{CH}_2\text{O})_2$  change over spontaneously into formic acid and formaldehyde respectively.

We wish to express our thanks to Imperial Chemical Industries, Limited, for grants to the laboratory with which the Spekker photometer and the diffusion pump were purchased.

### REVIEWS OF BOOKS.

**Optical Basis of the Theory of Valency.** By R. DE L. KRONIG. The Cambridge Series of Physical Chemistry. (Cambridge University Press, pp. i-x, 1-246. Price, 16s. net.)

Professor Kronig's book on *The Optical Basis of the Theory of Valency* deals with many topics which are already familiar to physical chemists, such as (i) the determination of intramolecular distances by X-ray analysis of vapours (Debye), or by the method of electron-diffraction (Mark and Wierl), (ii) the spectroscopic basis of the periodic classification, (iii) molecular spectra, including the isotope effect, and the determination of force constants and moments of inertia from the vibrational and rotational components of the spectrum, and finally (iv) the study of dissociation by spectroscopic methods, including the phenomenon of predissociation. This familiar material is, however, submitted to the chemist in an unusual form, since the author is himself a mathematical physicist. The chemical reader therefore finds himself subject to an unfamiliar discipline, and is given the opportunity of considering from a novel standpoint the foundations on which his science is built. It may be that the number of chemists who are qualified to benefit by this discipline is not large; but it is a real advantage that a book should be available, in which workers on the borderline between chemistry and physics may find the relevant material set out as clearly and accurately as in the present instance. It is also a solid advantage that the book is written in English, and is not so long as to impose an excessive burden on the reader. It can therefore be commended heartily to all chemists who would like to know what their science looks like in the eyes of a physicist, and also to physicists who wish to apply their own science to chemical problems.

T. M. L.

**Metastrukturen der Materie.** By PROFESSOR WOLFGANG OSTWALD. 16 pp. with 1 Figure; Dresden, 1935. Theodor Steinkopff. Price R.M. 0.80.

Those who have had the pleasure of listening to Professor Ostwald know well the dexterity with which he can produce an arresting phase in summarising what might be called the objectives of Colloid Science. In this monograph, an academic speech, we note the same breadth of philosophic treatment of the theme. It is with peculiar zest we remember that Professor Ostwald himself was one of those who in "those early days" defined colloids as the science of the Forgotten Dimension. This is not true now, the stone (or pyrogel) which the builders rejected is certainly now the headstone in the corner of our house. Colloids are now bristling with dimensions, and among organic substances they are the only ones which have the great advantage of presenting a real and tangible form and structure to the world.

The gaping void which existed between the terrestrial atoms and macro structures is now filled with colloids. It is interesting to speculate whether this seething abyss is the fons and origo of ourselves or represents nothing more than nature's garbage tin. Until recently it is true that the respectable organic chemist meeting a colloid would quietly pour it down the sink, but now the resins and plastics are saved and have to be synthesised and analysed. We as well as the resins and plastics are indebted to Professor Ostwald for this brave new world.

E. K. R.

**Colloids in Agriculture.** By C. E. MARSHALL, M.Sc., Ph.D. (London: Edward Arnold & Co. Pp. viii + 184. Price 5s. net.)

Dr. Marshall's knowledge and personal experience of colloids is a guarantee of the general soundness of this little book. It is planned in three sections. In the first an account is given in simple language of the main achievements of academic researches in the realm of colloids. The second part deals with colloids in the soil, and the third with colloids in plant and animal life. This way of arranging the subject matter has its drawbacks, the chief of which is that whereas a piece of academic research is described near the beginning of the book, it is not applied to anything connected with agriculture until near the end. In the intervening pages a host of other topics is discussed, and it needs considerable mental capacity to store up so many abstract ideas and then draw upon them one by one at a later stage. Some indeed are used so little that the student who is mainly interested in the agricultural side might justly feel that he had been persuaded to learn them under false pretences.

We cannot help feeling that the book would have been more readily assimilated by students of agriculture if it had been arranged in the reverse order, the colloidal behaviour exhibited by soil and the products of life being used to develop the fundamental notions the author wishes to instil. Such an approach would have produced a book corresponding better to the title.

The field covered is a wide one because agriculture is a many-sided occupation, and it is hardly to be expected that the book would be entirely free from errors. Two statements have caught our attention

which need correction. The first is that a plant which thrives in a hot, dry climate must lose very little water by evaporation from its leaves and must be able to take up water vapour from the air when the latter attains a greater humidity than usual; the second is that the isoelectric point of a protein is the point of minimum ionisation.

The author has a rather irritating way of discoursing on the views and feelings of "the physicist" and "the chemist." On page 45 we read, "But whereabouts in the solution shall we find these balancing ions? That is the question which tormented the physicists." It is difficult to see the purpose of such a remark.

R. KENWORTHY SCHOFIELD.

**Outline Notes on Telephone Transmission Theory.** By W. T. PALMER. Foreword by W. CRUIKSHANK. (London: Pitman (1936). Pp. 165. 22 cms.  $\times$  14 cms. Price 4s. net.)

Both author and publisher have made great efforts in this book on telephone transmission theory to meet the demands of a large body of engineering students. The book largely derives from the author's lectures at the Northampton Polytechnic Institute and the clarity of the printing and the writing, together with the blank pages for notes indicate that the average student's requirements have been very carefully considered. The book is divided into seventeen sections, and it is impossible in a short review to indicate the nature of the contents of all of these. The first two sections of the book are concerned with the building up of the necessary mathematical knowledge and the classical theory of electric wave propagation. The mathematical section should be taken rather as a revision course than a development from first principles, and Mr. Palmer gives adequate references to other more comprehensive works. Other important parts of the book deal with D.C. transmission, wave distortion in cables, artificial lines, transmission efficiency of telephone circuits, electrical wave filters, telephone repeaters, and unloaded ocean telegraph cables. The book closes with a good index and the sectional references to individual works should be valuable. Important derivations in the text are heavily underlined and one gets the impression, however unjust, that the student is being told perhaps just enough as is considered good for him without adequate regard for the great historical development of this subject; Heaviside gets one mention—in the foreword—and Kelvin receives a similar treatment in the text. This might be good enough for engineers but physicists will have a few words to say about it. The book is well printed on good paper. In turning over the pages it would be a good deal easier to see what was being discussed if the page legends corresponded to the section titles; instead of this we are treated to a repetition of the book-title.

J. T. R.

**Thermionic Emission.** By T. J. JONES. London: Methuen's Monographs on Physical Subjects (1936). Pp. viii + 108. 17  $\times$  11 cms. Price 3s. net.

Students and others anxious to obtain a readable survey on the subject of thermionic emission may find in this little work the kind of thing they require. The disadvantages of compression are most obvious when a more

comprehensive up-to-date work is already in existence. Jones's book is divided into six chapters; these include a theoretical survey, a discussion on experimental technique and others on atomic film emitters, oxide coated cathodes and the thermal emission of positive ions. The book would have been improved by a more critical attitude towards the many researches that are discussed. Mr. Jones's choice of phrase is sometimes a little unusual; surely "oxygenated tungsten" would be better than "oxidised tungsten" where monatomic films are concerned. The bibliography is extensive for a work of this scope.

J. T. R.

**Molekulspektren und ihre Anwendung auf chemische Probleme II.**

Text. By H. SPONER. (Berlin: Julius Springer. 1935. Pp. xii and 506. Price 36.0 RM. (Paper covers), 37.8 RM. (Bound).

This, the latest addition to the *Struktur und Eigenschaften der Materie* Series, is an exceptionally interesting volume, largely for the reason that it contains a great deal of information rarely found between the same two covers. Perhaps the basic characteristic of the Natural Philosophy of the past decade has been the ruthlessness with which pre-existing boundaries between physics and chemistry have been forcibly shifted, and in some instances obliterated. Thus, it is to be expected that a considerable amount of space would be needed to define the *status quo ante*, and this occurs in the first four chapters, which deal with the older quantum theory, quantum mechanics, molecular spectra and the use of band-spectra in the determination of the usual physical and chemical magnitudes. Some of the treatment, though very clear, suffers a trifle from over-compression, which is noticeable in the sections dealing with entropy and the chemical constant. Actually this is bound up with the formalism of the gulf which separates geometrical concepts (like the shapes of molecules) from pure thermodynamics, with their independence of mechanism.

The remaining chapters contain material of more direct concern to the physical chemist. An excellent survey of the spectroscopic criteria for atom-molecules, ion-molecules and polarisation-molecules will be found under the general heading of types of binding. The author then discusses the various theories in detail, following this up with chapters on molecular collisions, and some further applications of spectroscopy to chemical problems. The book concludes with a number of comprehensive tables, which together with the data contained in Part I. (see these *Transactions* 1935, 31, 1374), form a valuable work of reference. The writer is to be congratulated upon the freshness with which he develops his theme. There are references in plenty, but the text is not written round them; they appear at the right moment as apt illustrations, and never as pegs upon which to hang the usual comments.

The chemist of to-day tends to rely upon almost any method which gives him direct information about the molecule as such: spectroscopy (combined with magnetic analysis) is probably the most powerful, and Professor Sponer has shown clearly the great strides which have been taken in recent years.

F. I. G. R.

**Principles and Applications of Electrochemistry. Vol. II. Applications.**

By W. A. KOEHLER. John Wiley & Sons, Inc., New York; Chapman & Hall, Ltd., London. 1935. Pp. xiv + 545. Price 25s.

The long awaited second volume of *Principles and Applications of Electrochemistry*, the first part of which is already in its third edition (*Trans. Faraday Soc.*, 1936, **32**, 522), has now appeared under the authorship of Professor W. A. Koehler, instead of Colin G. Fink, whose multifarious activities have prevented him from undertaking the work. There is little doubt, however, that the publishers have secured an adequate substitute, and the new volume gives a satisfactory survey of the many applications of electrochemistry. The scope of the book may best be judged from the titles of the chapters, which are as follows: Economics of Power Generation; Review of Theoretical Electrochemistry; Primary Cells; Secondary Cells; Electroplating; Electroplating Solutions; Electrorefining of Metals; Electrometallurgy—Aqueous Solutions; Electrometallurgy—Fused Electrolytes; Electrolysis of Alkali Halides; Electrolytic Oxidation and Reduction; Hydrogen and Oxygen; Corrosion; Electroanalysis; Electric Furnaces—General; Electric Furnaces in the Metallurgical Industries; Electric Furnaces in the Non-Metallurgical Industries; Electronics; Ozone; Fixation of Atmospheric Nitrogen; Separation by Electrical Means; and Miscellaneous Electrochemical Processes.

To cover such a vast amount of ground in the course of some 500 pages, many of which are largely occupied by figures, means, of course, that the treatment is often superficial, but there are frequent references to the literature where further information can be found. The author is indeed to be congratulated on the extent and variety of the information which he has succeeded in collecting and collating. The book is partly intended as a text-book for students, presumably technological, and partly as a reference work for those in industry: it should prove of great value to both types of readers if they wish to become acquainted with the scope of applied electrochemistry, without requiring great detail. The author sometimes forgets that this book is a companion to one devoted to the principles of electrochemistry, as is evident from the 43 pages of "Review of Theoretical Electrochemistry," but his object was, no doubt, to make the work self-contained and complete in itself. The production of the book is excellent, and the descriptive matter is illustrated with 244 diagrams and photographs: it is altogether a work to be commended.

S. G.

# A RAPID MICRO-METHOD FOR THE DETERMINATION OF MELTING-POINT.

BY R. C. RAY AND V. DAYAL.

*Received 27th January, 1936.*

The determination of melting-points of substances which fuse at high temperatures, especially of inorganic salts, is a tedious operation. The present paper describes a simple and rapid method for determining the melting-points of minute quantities of solid substances. McDavid<sup>1</sup> measured the ignition temperatures of gaseous mixtures by means of an electrically heated spiral of platinum wire, the temperature of which was obtained by passing a known current, which was determined with an ammeter. It appears, however, that the method has not received the wider application which it deserves. McDavid's method has been adapted to the measurement of melting-points. Preliminary experiments seem to show that the method would also be applicable to determinations of freezing-point—solubility of solids.

The apparatus required is quite simple, and is shown diagrammatically in Fig. 1. A small piece of platinum wire is bent so as to form a point W.

The two ends of the wire are sealed to short pieces of glass tubing and electrically connected by means of mercury to the battery B, through two sliding resistances, R and  $R_1$ , the milliammeter A and the switch key K. A minute quantity of the finely-powdered solid, the melting-point of which has to be determined, is spread in as thin a layer as possible upon the mica platform P which can be raised or lowered as necessary. The platinum point W is made to touch a tiny particle of the solid whose fusion is observed through the telescope T. The platinum point is heated by the current from a storage

FIG. 1.

battery of 24 volts but of high capacity so as to obtain no fluctuation in the current during an experiment. The melting temperature is first roughly adjusted by the resistance R, the final adjustment being made by the finer sliding resistance  $R_1$ . The current necessary to raise the platinum point to the temperature of fusion is measured by the milliammeter. In the preliminary experiments a platinum spiral was used and the powdered

<sup>1</sup> *J. Chem. Soc.*, 1917, 111, 1003.

substance was dusted on the spiral, but it was found that at the melting-point the molten substance spread, causing a short circuit.

The results obtained with 10 inorganic salts, which had been carefully purified by recrystallisation, are given in the following Table :—

Substance. . .	CdCl <sub>2</sub> .	KIO <sub>3</sub> .	CdBr <sub>2</sub> .	KI.	KBr.	KCl.	NaCl.	Na <sub>2</sub> CO <sub>3</sub> .	SrCl <sub>2</sub> .	K <sub>2</sub> CO <sub>3</sub> .
Current in amps. .	2.147	2.150	2.164	2.330	2.416	2.474	2.519	2.587	2.608	2.647
Melting-point C. (observed)	558°	560°	569°	680°	737°	776°	806°	851°	865°	891°
Melting-point C. (International Critical Tables)	568°	56(0°)	583°	773°(?)	7(30°)	×	804°	851°	873°	891°

A large number of determinations of the melting-point of each substance was made, and the values recorded above represent the mean of these results. The greatest difference obtained in the value of the current to attain the melting-point of any one substance was never more than 0.005 amps., which corresponds to a temperature difference of 3 to 4 degrees, and therefore  $\pm 4^\circ$  may be regarded as the experimental error. The melting-point recorded in the International Critical Tables, Vol. I, 1926,

FIG. 2.

is also included for comparison. It should be pointed out in this connection, that there exists a considerable amount of discrepancy regarding melting-points of inorganic compounds; different melting-points have been obtained for the same substance by different investigators. Several workers, for example, have found 680° as the melting-point of potassium iodide, while the Critical Tables give the value 773°, which is certainly not the correct temperature.

The heating currents are plotted against the melting temperatures in Fig. 2. In obtaining the graph, the melting-points of three substances, which had been especially purified and whose melting-points had been previously determined by other methods, were taken as standards, and

temperatures corresponding to the observed heating currents gave the melting-points of other substances. It will be noticed that the relationship between the heating current and the melting-points is a straight line, and for it the equation  $C = M \times 0.0015 + 1.310$ , where  $C$  is the heating current and  $M$  is the melting temperature, holds, so that when the apparatus is once set up, the melting-point of any substance may be readily obtained by simply measuring the current passing through the platinum point when the substance just begins to melt. The great advantage of the method is that only a minute quantity of the substance is required for the determination of the melting-point.

## THE DISSOCIATION CONSTANT OF HYDROCHLORIC ACID.

BY ROBERT A. ROBINSON.

*Received 30th December, 1935.*

One of the most important arguments in favour of the complete dissociation of strong electrolytes is to be found in the extremely small partial vapour pressures of the hydrogen halides in moderately dilute aqueous solution. Wynne-Jones<sup>1</sup> has utilised this small vapour pressure to calculate the dissociation constant of hydrochloric acid by assuming that Raoult's law gives the mole fraction of undissociated hydrochloric acid as the ratio  $p/p_0$ , where  $p$  is the partial vapour pressure in aqueous solution and  $p_0$  the vapour pressure of pure hydrogen chloride at the same temperature. Hence Wynne-Jones concluded that the dissociation constant of hydrochloric acid at 0° is  $2.5 \times 10^7$ . As this acid is so often quoted as an example of complete dissociation, it is worth while utilising the vapour pressure data at other concentrations and temperatures, for the argument will be more convincing if it can be shown that the "dissociation constant," calculated in this way, is constant over a range of concentration and varies in the expected manner with temperature.

I have used the partial vapour pressure data at 0°, 10°, 20°, 25°, 30°, 40° and 50°, recorded in the International Critical Tables,<sup>2</sup> over the concentration range 0.56-15.4 *M*-HCl as well as the vapour pressure of pure hydrogen chloride at these temperatures.<sup>3</sup> In addition the data of Dunn and Rideal<sup>4</sup> at 25° have been used to obtain points at low concentrations. From these the mol. fraction of undissociated hydrochloric acid was calculated and thence the dissociation constant from the equation:

$$K = \frac{a_{\text{HCl}}}{[\text{HCl}]},$$

$[\text{HCl}]$  being the mol. fraction of the undissociated component and  $a_{\text{HCl}}$  and  $a_{\text{Cl}}$  being calculated from the activity coefficient data of Randall and Young.<sup>5</sup> Two assumptions are made: (1) that the activity coeffi-

<sup>1</sup> *J. Chem. Soc.*, 1930, 1064.

<sup>2</sup> *I.C.T.*, III., p. 301.

<sup>3</sup> *Ibid.*, p. 228.

<sup>4</sup> *J. Chem. Soc.*, 1924, 125, 676.

<sup>5</sup> *J. Amer. Chem. Soc.*, 1928, 50, 989.

cient of the undissociated acid is unity, (2) that the activity coefficients of the dissociated parts do not vary with temperature. Both these errors will diminish with increasing dilution, but whereas the former is not likely to be affected appreciably by temperature, the second error may even change its sign with a temperature increase. Fig. 1 shows the results of these calculations.

From this figure it is evident that the effect of the two errors mentioned above are at a minimum at 20°, 25° and 30° and extrapolation gives a probable value for  $K$  at these temperatures. The fact that at 0° and

FIG. 1.—Variation of the dissociation constant of hydrochloric acid with concentration and temperature.

10°  $K$  decreases with increasing acid concentration whereas the converse is true at 40° and 50° is probably due to the changing value of the ionic activity coefficients. In view of the experimental difficulties involved in determining partial vapour pressures at low concentrations the 'constancy' of  $K$  is all that

can be expected. The following values are obtained by extrapolation for the dissociation constant, the concentrations being measured in the more usual units of gram mols. per 1000 g. of water.

° C.	0	10	20	25	30	40	50
$K \times 10^{-4}$	20	6.8	2.4	1.3	0.72	0.28	0.12

If  $\log K$  is plotted against  $\frac{1}{T}$  the points lie on a straight line whose slope gives the thermal changes associated with the complete process of dissociation as 17,900 cal. As  $K$  diminishes with a rise in temperature, i.e., temperature favours the formation of the undissociated molecule, this amount of heat must be evolved in the process of dissociation. It is to be anticipated that the dissociation would be highly exothermic in view of the extent to which the reaction proceeds.

### Summary.

The calculation of the dissociation constant of hydrochloric acid from partial vapour pressure data has been extended to a wider range of concentration and temperature. The thermal changes associated with the complete process of dissociation of hydrochloric acid are found to be 17,900 cal. (evolved).

# A STUDY OF THE CRYOLITE-ALUMINA CELL WITH PARTICULAR REFERENCE TO DECOMPOSITION VOLTAGE.

BY J. W. CUTHBERTSON, M.Sc.,\* AND J. WADDINGTON, M.Sc.

*Received 10th December, 1935.*

The earliest research on the theory of the electrolytic process for the extraction of aluminium from alumina-cryolite baths appears to have been undertaken by F. Haber<sup>1</sup> and his collaborators who, working on the laboratory scale, endeavoured to show that the electrolysis obeyed Faraday's laws. Their efforts were unsuccessful, failure probably being attributable to the formation of metal fog. Furthermore, the effects of secondary electrode reactions and mixing of the primary products by convection currents, factors which are relatively far more important in small-scale experiments than in industrial cells, were not fully appreciated. By weighing the anode before and after an experiment, F. Haber and R. Geipert<sup>2</sup> found that a little more than 0.66 grm. of electrode material was consumed in the production of 1 grm. of aluminium, and as this agrees with the equation :

concluded that this reaction correctly expressed the cell decomposition. For a long time the view was held that economy in anode consumption was thus definitely limited.

In 1916 G. H. Bailey<sup>3</sup> suggested that the above reaction did not truly represent the electrolysis, for in the first instance the gases evolved from the cell normally contain a large proportion of carbon dioxide, and secondly, the weight of carbon actually consumed in the process is insufficient to account for the formation of carbon monoxide alone. The following year, R. Seligman<sup>4</sup> published analyses of anode gases from an experimental furnace. In one case the carbon dioxide content was 45.6 per cent. and carbon monoxide 43.6 per cent. Raising the operating temperature by 110° C. decreased the quantity of carbon dioxide in the gases and increased both the carbon monoxide content and anode consumption. J. D. Edwards, F. C. Frary and Z. Jeffries<sup>5</sup> suggested that an even higher carbon dioxide figure applied to the working of industrial cells. They put the limits at 50-90 per cent. Seligman's original view was that oxygen was primarily formed, according to the equation :

and that "whether oxygen, carbon dioxide or carbon monoxide resulted was dependent upon such factors as temperature, current density, physical properties of the carbon anode, rapidity with which the gases

were removed from contact with the anode and similar factors." Bailey, on the other hand, believed that carbon dioxide was first formed, thus:

for under favourable conditions the proportion of this gas present may be very large, in spite of the fact that at the temperature of the cell the equilibrium:

is well over towards the right-hand side.

Later work on the cell decomposition voltage has shown that the carbon exerts a depolarising effect, reducing the voltage required for decomposition. The formation of oxides of carbon is an inherent characteristic of the electrolysis, and hence it is probable that the true conditions are represented by a combination of reactions (2) and (3) with the latter predominating under normal conditions.

The decomposition voltage may be determined experimentally but the practical difficulties involved are considerable, and consequently several investigators have attempted to calculate its value from thermodynamical data. J. W. Richards,<sup>6</sup> in 1903, calculated 2.3 v. as the decomposition voltage for an unattackable anode. This result, taken in conjunction with his figure of 0.6 v. for the depolarisation arising from the use of a carbon anode, agrees almost perfectly with his experimental findings. G. Gin,<sup>7</sup> using Le Blanc's commutator method, obtained a value of 2.3 v., whilst J. W. Langley<sup>8</sup> working along very similar lines, observed the much lower figure of 1.2 v. at 1010° C. P. P. Fedotieff and W. Iljinsky,<sup>9</sup> in a general account of the electrometallurgy of aluminium based upon an exhaustive investigation of the process, have attempted to explain these discrepancies. Although they were unable to obtain characteristic curves for the voltage-current relationship, they noticed that electrolysis started well below 2.0 v. and claimed to have observed the formation of particles of aluminium, accompanied by gas evolution at the anode, at 1.2-1.3 v. They concluded that the metal so liberated reacted with the carbon to form aluminium carbide, and hence permanent metal separation would not occur until the voltage was increased considerably, the actual figure given being 2.2 v. In support of this view, it may be said that the voltage corresponding to the energy of formation of the carbide has been calculated by Berthelot to be 0.9, so that if aluminium is permanently liberated at 2.2 v. the carbide should form at a potential of 1.3 v. Fedotieff and Iljinsky, however, state that the metallic particles first set free react with the carbon with almost explosive violence, and in view of more recent work, it would appear highly probable that this phenomenon is due at least in part, not to the formation of aluminium carbide, but to simple oxidation of the metal. Consequently, *permanent* metal separation may begin at as low a voltage as 1.2.

In 1927 P. Drossbach<sup>10</sup> gave 2.565 v. for the decomposition voltage of a cell having inert anodes but later, for a saturated solution of alumina in cryolite at 927° C., recorded the lower value of 2.16 v.<sup>11</sup> Comparatively recently A. B. Newman and G. G. Brown,<sup>12</sup> in America, have

calculated values of 2.04 v. and 2.06 v. for saturated and half-saturated solutions respectively, the temperature in each case being 950° C. These authors have also computed the depolarisation arising from oxidation of carbon anodes and state that the decomposition voltage may thereby be reduced to 0.947 v.

The decomposition voltage  $E$  at any given temperature may be calculated from the formula:

$$E = \frac{\Delta F}{nf} = \frac{\Delta F}{138,444} \text{ volts} \quad (1)$$

where  $\Delta F$  is the free energy of formation of alumina from aluminium and gaseous oxygen at that temperature. For any given temperature  $T$ ,

$$\Delta F = \Delta H - T\Delta S$$

where  $\Delta H$  is the heat of the reaction:

and  $\Delta S$  is the change in entropy. At constant pressure the change in free energy with temperature is:

$$\Delta F_T = \Delta F_{298} - \int_{298}^T \Delta SdT.$$

The last term is conveniently evaluated by graphical integration of the entropy-temperature curve derived from existing data, and hence  $\Delta F_T$  can be found and  $E$  for any temperature calculated from equation (1). The heat of combustion of aluminium has been determined with renewed care by A. Meichsner and W. A. Roth,<sup>13</sup> who obtained the value of  $393,300 \pm 400$  cal. at 20° C. and constant pressure. They attribute their former low result, used by Drossbach, and also by Newman and Brown in their calculations, to exothermic reactions resulting from ignition in clay boats. Taking the above value of  $\Delta H$ , for a saturated solution of alumina in cryolite, the theoretical decomposition voltage at the normal working temperature of 960° C. becomes 2.16 v. For any other alumina concentration  $C_1$  the decomposition voltage will be:

$$E_1 = E + \frac{RT}{nf} \ln \frac{C}{C_1}$$

where  $E$  is the calculated voltage for a solution of concentration  $C$ . Within limits, the effect of a reduction in concentration is not very pronounced. Thus,

$$\begin{aligned} E_1 &= E + 0.012 \text{ for a half saturated solution} \\ &= E + 0.024 \text{ for a quarter saturated solution.} \end{aligned}$$

From data given by Eastman,<sup>14</sup> the depolarisation by graphite has been calculated. Assuming a temperature of 950° C., the figures found are:

$$\begin{aligned} E &= 0.99 \text{ volt. } (\text{C} + \text{O}_2 \longrightarrow \text{CO}_2) \\ E &= 1.10 \text{ volt. } (\text{C} + \text{O} \longrightarrow \text{CO}). \end{aligned}$$

The depolarisation should therefore lie somewhere between these limits. Taking Edwards, Frary and Jeffries' estimation of the composition of furnace gases found in works practice, i.e. 50-90 per cent.  $\text{CO}_2$ , it would appear as though 1.0 volt would be a reasonably accurate figure to adopt.

Investigation of the conductivity of the molten cryolite bath is beset with even greater practical difficulties than is the determination of the decomposition voltage, consequently it is not surprising that the amount of work published on the subject is small. The accuracy attainable with ordinary a.c. bridge methods depends largely on the absolute value of the resistance to be measured, and is of a relatively low order when the total cell resistance, that is, the resistance of cell plus liquid, is low. It is desirable, therefore, that the value of the total resistance should not be less than approximately 10 ohms, and hence the container should preferably be of some non-conducting material. Unfortunately, the extremely corrosive nature of molten cryolite introduces a complication and most, if not all, of the feebly conducting refractories available for the container are rapidly attacked.

K. Arndt and W. Kalass,<sup>15</sup> using a platinum crucible and central disc electrode, determined the specific resistance of cryolite at 1000° C., obtaining a value of 0.448 ohms per cm.<sup>3</sup> As alumina was added to the melt, the conductivity fell almost linearly and, by extrapolation, became zero at 100 per cent. alumina. Also the equivalent conductivities of cryolite and sodium fluoride were found to be approximately equal, and hence it was concluded that the alumina acted as solvent and the cryolite as ionised solute, the conductivity being attributed to the rapidly migrating sodium ion, the anion  $\text{AlF}_6'''$  being assumed to move slowly. In these experiments, the resistance of the cell was only of the order of 0.3 ohm and, therefore, the accuracy of the results is open to question, particularly as the authors themselves admit some difficulty in balancing the bridge. Furthermore, the possibility of alumina additions leading to the formation of aluminate incrustations on the walls of the crucible or central electrode must not be overlooked, and as the resistance of the cell would thereby be increased, this factor might have a profound effect on the observed increase in specific resistance referred to above.

In the case of the decomposition voltage, the inherent difficulties associated with its determination are no doubt largely responsible for the discrepancies between the results of different investigators. The same probably applies to conductivity measurements. The present work was undertaken mainly to obtain further information on these two important factors. The greater portion of the work is devoted to the determination of the decomposition voltage of cryolite and cryolite-alumina mixtures, but a few experiments on the conductivity of molten cryolite have also been completed.

#### Determination of the Decomposition Voltage.

The industrial type of aluminium cell, in which the bath is maintained in a molten state by the Joule effect of the current traversing it, is unsuitable for research purposes. Compared with large units the heat losses from small cells are relatively very much greater, therefore to prevent the bath from freezing the current must be increased. This leads to excessively high anode and cathode current densities and the final conditions may be totally different from those under which the technical process is operated. Furthermore, temperature control of small baths with internal electric heating is difficult, and the temperature is not uniform throughout the melt. All of these disadvantages may be overcome by applying external heat to maintain the bath temperature, and as the electrolysing current is then independent of the heating, the former may be varied at will.

<sup>15</sup> *Z. Elektrochem.*, 1924, **30**, 12.

In the present work the electrolysis was carried out in a carbon crucible heated in an electric furnace having a resistor element of nichrome tape wound on a 4-in. diameter sillimanite tube, a refractory which resists fairly well attack by the vapours evolved from the melt. For the majority of the experiments a graphite crucible was employed, but as amorphous carbon is used in industrial cells, crucibles of this material were also tried out. On the whole, the graphite and amorphous carbon containers gave substantially the same experimental results, but the latter absorb the greater amount of electrolyte, have the higher specific resistance, and disintegrate more rapidly than graphite crucibles.

For the manufacture of the pots, 3-in. diameter graphite rod was machined to the form shown in Fig. 1, the cavity being made slightly conical to facilitate removal of the solidified melt. Nichrome tape, freed from oxide, inserted into holes bored in the crucible walls and plugged firmly with carbon rods, served to make a sound electrical connection. A third hole was also provided to house the thermocouple sheath. Undue volatilisation of the charge was prevented by a lid of baked alundum cement, through the hole in which the central electrode was inserted. During melting this electrode was withdrawn and the aperture in the lid closed by a smaller alundum disc, thus effectively sealing the crucible and reducing the losses to a minimum.

The simplest and most direct method of determining the decomposition voltage is from current-voltage curves. By using the crucible as one electrode in conjunction with a small point electrode which may be either the anode or the cathode, it is possible to obtain the discharge potentials of the respective anions and cations.

For the construction of the central electrode, details of which are given

FIG. 1.

FIG. 2.

in Figs. 1 and 2, a short length of  $\frac{1}{8}$ -in. diameter graphite rod was forced tightly into a hole bored axially in a larger carbon rod, the protruding end being ground to a blunt point. The ratio of the areas of the two electrodes actually in contact with the melt was 20:1. Protection of the large central rod was afforded by the application of two or three coats of a paint made from powdered carborundum and a 25 per cent. solution of sodium silicate, a mixture which is very effective in preventing undue oxidation.

The crucible was supported inside the furnace on a short length of silica tube but separated therefrom by sheet mica, thus ensuring, so far as possible, electrical insulation from the furnace winding.

A diagram of the circuit used for the current-voltage determinations is reproduced in Fig. 3. Current for electrolysis was drawn from a 10-volt accumulator service, the necessary variation in voltage being provided by the potential divider  $R_1$  and series resistance  $R_2$ . Switch  $S_1$  is for the purpose of reversing the polarity of the cell, and by means of  $S_1$  connection may be made between the cell and either the current source or the Wheatstone bridge on the left. The instruments  $A$  and  $V_1$  indicate the current

FIG. 3.

and voltage respectively. The voltmeter  $V_2$ , of greater sensitivity than  $V_1$ , may be introduced as required by the switch  $S_3$ , its range depending on the adjustment of the variable resistance  $R_2$ .

To obtain a true value for the voltage expended in decomposition, the voltage drop in the leads, electrodes and electrolyte itself must be known. The a.c. resistance of the cell circuit was determined by means of the Wheatstone bridge in conjunction with alternat-

ing current supplied from a separate valve oscillator. Since the resistance to be measured was only of the order of half an ohm the resistance of the bridge circuit should also be low and any small capacities must be balanced out. A standard 1 ohm resistance shunted by a variable condenser  $C$  was used in the second arm of the bridge.

The valve oscillator circuit is reproduced in Fig. 4. The rotary switch  $S$  is connected to tappings on the anode coil. As its contact revolves two distinct notes of different frequency are repeated at regular intervals in the 'phones, and it then becomes a relatively simple matter to balance the bridge, no additional amplifier being required.

In conducting an experiment, sufficient cryolite or cryolite-alumina mixture in the form of powder is put into the crucible, which is then covered with the lid, and the whole placed in the furnace previously heated to about  $1000^\circ\text{C}$ . When molten the charge is stirred and, as soon as the temperature becomes steady at the value decided upon, the resistance is measured. The next procedure is the determination of the current-

voltage curve which is completed step by step, the voltage being adjusted each time by manipulation of  $R_1$  and  $R_2$ . Readings of current and e.m.f. are taken as soon as a steady state is reached. Except when the voltmeter  $V_1$  is in use,  $V_1$  may conveniently be left permanently connected across the cell circuit and, if after recording, the circuit is broken by means of  $S_1$ , the cell back e.m.f. will be given directly by this instrument. It should be emphasised that, although  $V_1$  is of lesser sensitivity than  $V_2$ , its internal resistance is sufficiently high to ensure the effect on the deflections of  $A$  being immeasurably small.

If the back e.m.f. does not die away quickly enough, the cell is short-circuited by closing the switch  $S_4$ . When the applied voltage is low, this is usually unnecessary, but beyond a certain value some considerable time elapses before the back e.m.f. entirely disappears.

The length of time occupied in taking a large number of readings gives ample opportunity for the resistance and composition of the electrolyte to alter, and accordingly a limited number of accurate readings is preferable to more numerous hurried observations. On the completion of a series of readings the resistance of the circuit was always rechecked, and if there was evidence of any appreciable change the results of the experiment were discarded.

If the small central electrode is made the anode the resistance after electrolysis can only be restored to the original value, and the bridge satisfactorily balanced, by passing a current through

FIG. 4.

the cell in the reverse direction for a short time. Unless this is done, an approximate balance only can be obtained, corresponding to a cell resistance very much above that initially recorded.

When the applied potential difference exceeds some 2 v., on switching off the current the back e.m.f. falls rapidly to about 1 v., remaining stationary just below this value before finally dropping quickly to zero. The instrument  $V_1$  was installed specifically to investigate this phenomenon, and enabled the rate of fall of back e.m.f., after applying a certain fixed voltage for perhaps 20 seconds, to be followed closely. Curves obtained in this manner (see Fig. 10) show a definite peak, the magnitude and position of which depend upon the bath temperature and composition. This, however, only applies to those cases in which the small electrode is the cathode. If made the anode the back e.m.f. dies away almost instantaneously.

#### Determination of the Conductivity of Molten Cryolite.

Attempts to measure the conductivity along the lines developed by Arndt and Kalass, but substituting a graphite container for their platinum

that heat would fuse the aluminium silicate causing it to block the pores proved unsuccessful, the clay apparently interfering with the sintering process.

A number of experiments was carried out with so-called fused magnesia tubes. Even this material is porous, and also tends to dissolve slowly in the melt. The porosity may be reduced by an initial soaking in a hot saturated solution of magnesium nitrate followed by ignition at a high temperature. Sintered corundum ( $\text{Al}_2\text{O}_3$ ) linings for electrolytic cells have been used by P. Drossbach,<sup>16</sup> but the mechanical properties of this material are poor, and although not rapidly dissolved by cryolite already containing alumina, its contaminating effect on the pure flux renders it less suitable than magnesia for conductivity cells.

The construction of the cell is clearly outlined in Fig. 5, which is self-explanatory. The complete cell, which may be some 5 or 6 in. in length, is conveniently heated in the furnace previously illustrated (Fig. 2). When the required temperature is reached, the cell is filled with molten cryolite and resistance and temperature measurements taken. The cell is then withdrawn, emptied and returned to the furnace for determination of the resistance of cell plus connecting leads. A final measurement of the total resistance when the cell is filled with molten copper-aluminium alloy allows the resistance of the leads to be determined. The cell constant may be calculated fairly accurately from the linear dimensions. The area of cross-section is best determined by weighing the tube, of which the length is known, both before and after filling with mercury.

The figures recorded below will serve as a typical example of the application of this cell to conductivity measurement:—

Length of tube	= 10.29 cm.
Area of cross-section	= 0.774 cm. <sup>2</sup>
Cell constant	= 0.0752
Temperature	= 1020° C.
Resistance of cell + leads — cryolite ( $R_1$ )	= 4.9 ohms.
Resistance of cell + leads ( $R_2$ )	= 185.5 ohms.
Resistance of cell + leads + metal ( $R_3$ )	= 0.219 ohm.
(When filled with highly conducting metal the re-resistance of the cell plus charge will be so low that it is legitimate to neglect it. Hence $R_3$ becomes the resistance of the leads.)	
Resistance of cell ( $R_2 - R_3$ )	= 185.28 ohms.
Resistance of cell + cryolite ( $R_1 - R_3$ )	= 4.68 ohms.
Resistance of cryolite $\left( \frac{1}{\frac{1}{(R_1 - R_3)} - \frac{1}{(R_2 - R_3)}} \right)$	= 4.80 ohms.
Specific resistance of cryolite at 1020° C.	= $4.8 \times 0.0752$ .
	= 0.361 ohm per cm. <sup>3</sup>

### Discussion of Results.

Two typical current-voltage curves selected from a series obtained with a small cathode are reproduced in Fig. 6. In every case investigated the curve showed a number of distinct breaks, ultimately becoming parallel to the line representing resistance, that is, to  $R$ ,  $R$  in the figure. The actual values corresponding to the various discontinuities in the particular cases here represented are given in Table I., where  $E$  is the observed e.m.f. and  $E_s$  is the true or corrected value, derived from the equation:

$$E_s = E - IR,$$

$I$  being the electrolysing current and  $R$  the resistance as measured by the bridge.

<sup>16</sup> *Z. Elektrochem.*, 1934, 40, 605.

TABLE I.—POSITION OF BREAKS IN CURRENT-VOLTAGE CURVES. TEMPERATURE 1025° C.

Cryolite.			Cryolite + 16 per cent. Alumina.		
$E$ , Volts.	$I$ , Amps.	$E_b$ , Volts.	$E$ , Volts.	$I$ , Amps.	$E_b$ , Volts.
0.99	0.11	0.93	0.56	0.03	0.54
1.90	0.60	1.55	1.12	0.23	1.01
2.25	0.99	1.68	1.78	0.74	1.41
			2.38	1.80	1.48
$E_d = 1.70$ volts.			$E_d = 1.51$ volts.		

Taking firstly the results for fused cryolite at 1025° C., three breaks are discernable, dividing the curve into four sections, the positions of the first and last breaks especially showing extremely close agreement in the case of all the curves for this and also for other charges. The first branch of the curve is almost horizontal, and what little current passes is probably due to continuous depolarisation—the applied voltage is below the deposition voltage of the cation, hence there is no deposition and no back e.m.f. Only a limited current can flow in this way, for if the current

FIG. 6.—Current-voltage curves obtained with a small cathode. Temp. 1025° C.

density is increased the voltage at the electrode rises above the deposition value of the cation which consequently is deposited. When this occurs, more current flows, increasing in value proportionately to the potential difference in excess of the deposition voltage, and the second stage of the curve is entered upon. During this period, the current falls gradually soon after switching on, and continuous electrolysis is, therefore, impossible. The results plotted in the curves were all taken immediately after the commencement of electrolysis, a precaution which, if conditions are liable to change with time, is clearly essential. The second break, which would appear to indicate the presence of two cations in molten cryolite, is succeeded by the third and fourth stages in which the current becomes much steadier and the back e.m.f. falls slowly. The last branch of the curve is approximately parallel to the line representing resistance, indicating that the full conductivity of the melt has been developed, both cations and anions taking part in current conductivity. The value found by producing this part of the curve backwards to cut the voltage co-ordinate at  $E_d$  is the total decomposition voltage of fused cryolite at 1025° C., and should theoretically be equal to the corrected voltage corresponding to the last break in the curve.

The authors made several abortive efforts to compound a synthetic cryolite having properties similar to those of the natural product. It was anticipated that investigation of the behaviour of the synthetic material would shed light on the mechanism of electrolysis previously studied, but the experiments proved to be disappointing. Sodium and aluminium fluorides were mixed in the proportions demanded by the composition of cryolite ( $3\text{NaF} \cdot \text{AlF}_3$ ), and after melting in the crucible, a current-voltage curve was taken in the usual manner. In every case the curves for the synthetic and the natural materials differed, and in particular it was observed that, in the former case the voltage corresponding to the peak in the back e.m.f. curve was markedly reduced. On concluding an experiment the melt was analysed, the average results being given in Table II.

TABLE II. ANALYSIS OF CRYOLITE.

	Fluorine.	Sodium.	Aluminium.
Synthetic	46.0 per cent.	33.0 per cent.	13.5 per cent.
Natural	54.28 ..	32.84 ..	12.81 ..

In the first case the missing 7.5 per cent. is probably due to oxygen (not estimated), present in combination with a part of the aluminium forming alumina. Fedotieff and Iljinsky<sup>9</sup> have found that aluminium fluoride readily absorbs water which, owing to hydrolysis, cannot be removed by heating in air, thus:

As it is apparently very difficult to obtain the fluoride absolutely free from water, there will always be the danger of heat converting the synthetic mixture into a dilute solution of alumina in the double fluoride, which probably accounts for the observed discrepancies between the current-voltage curves of the two materials.

Turning now to cryolite-alumina melts, attention was concentrated on a mixture containing 16 per cent. of alumina, which, although somewhat richer than is employed industrially, has a relatively low melting-point and therefore allows increased latitude for exploration. The composition is approxi-

FIG. 7.—Current-voltage curve of a 16% alumina-cryolite melt obtained with a small anode. Temp.  $1025^{\circ}\text{C}$ .

mately that of the cryolite-alumina eutectic. The cathode current-voltage curve for this mixture differs from that for cryolite, there being evidence of a greater number of discontinuities of which the first occurs at a lower value than the corresponding break in the cryolite curve. Excluding the

first and last breaks, the position of the other discontinuities in the curves of all cryolite-alumina mixtures examined, up to 24 per cent. alumina content, was not so definite as in the case of curves obtained from pure cryolite melts.

The anodic curve for the 16 per cent. alumina melt is reproduced in Fig. 7, and the effect of temperature on the relative positions of the discontinuities in both the cathodic and anodic curves is illustrated by Fig. 8.

FIG. 8.—Effect of temperature on decomposition voltage of cryolite and cryolite-alumina melts.

of increase in alumina content on the cathodic and anodic voltages. From 8 per cent. alumina upwards there is only a slight increase in total decomposition voltage, as would be anticipated from theoretical considerations. The anodic voltages were determined from the position of the break in curves obtained with a small anode.

The back e.m.f. after electrolysis becomes approximately constant at 1.3-1.4 v. in the case of cryolite, and at 1.2-1.3 v. when the melt contains 16 per cent. of alumina. Back e.m.f. curves are included in Fig. 6, but more interesting results can be obtained by plotting the inverse rate of fall of e.m.f. against cell voltage, as shown in Fig. 10. In general form these curves resemble that which would be obtained from a secondary cell undergoing discharge through a fixed resistance, the peak voltage corresponding to the free energy of the reaction taking place. Although the quantity of electricity passed through the cell during electrolysis may be the same in every case, the magnitude of the peak is found to vary considerably with the composition of the charge.

The fact that no corresponding peak is found in the anodic curves seems to indicate that the form of these curves is associated with the accumulation of some product at the cathode, either sodium or aluminium. As the authors are unable to find evidence of a peak in the cathodic curve of sodium fluoride, the phenomenon must be attributed to the presence of aluminium. The diminution in the size of the peak resulting from addition

The temperature coefficient of the experimentally determined decomposition voltage, *i.e.*, the slope of the curve I. in the figure, is apparently greater than that found for cryolite, curve IV. It is quite possible, however, that the high results for the lower temperatures are attributable to incomplete solution of the alumina, and it is suggested that the dotted line, curve III., may more accurately represent the true state of affairs.

Fig. 9 shows the effect

FIG. 9.—Change in decomposition voltage of a cryolite-alumina melt with increasing alumina content. Temp. 1025° C.

of alumina is not easily explained. In a manner at present not fully understood, alumina apparently tends to suppress the reversion of the cathodic product to the ionic state. Many back e.m.f. curves were plotted for melts of increasing alumina content, and the magnitude of the peak was found to reach a minimum value when the bath contained between 8 per cent. and 12 per cent. of alumina. Further alumina additions, up to 24 per cent., have no effect on peak dimensions, but there is a slight progressive lowering of the e.m.f. at which the peak occurs. It is significant that the ratio of alumina to cryolite in the melt giving the minimum arrest in the back e.m.f. curve agrees fairly closely with the composition of charge corresponding to the minimum in the decomposition voltage-alumina content curve, Fig. 9.

It was not originally the authors' intention to investigate in detail the behaviour of salt baths having unattackable anodes, but in view of a paper on depolarisation in the electrolysis of alumina, published by M. de K. Thompson and R. G. Seyl<sup>17</sup> since the completion of the experimental part of this work, further tests were undertaken. The graphite anode previously used was replaced by a stout platinum wire welded to a staybrite rod, the

FIG. 10.—Effect of increase in alumina content on rate of fall of back e.m.f. after electrolysis.

remainder of the equipment being unchanged. Current-voltage curves for both cryolite and cryolite-alumina melts at 1025° C. were taken in the usual manner. Table III. gives the results derived from these curves, together with the average of those previously obtained with graphite anodes.

In the last case, the anodic depolarisation is 0.7 volt, which is somewhat lower than Thompson and Seyl's figure, viz., 0.87 volt, and still less than their calculated value of 1.15 volts—facts which support the conclusion that the depolarisation does not readily attain its full value, but varies probably with the condition of reactivity of the carbon. The figures for the decomposition voltage with carbon anodes are in reasonable agreement with the results published by Edwards, Frary and Jeffries representing works practice.

It is interesting to note that the electrolysis of fused cryolite with a platinum anode leads to very rapid destruction of the latter, whereas a similar anode immersed in a 16 per cent. alumina-cryolite melt for an hour, passing a current of 3 amps., was visually quite unaffected. In the former case the attack is undoubtedly due to fluorine liberated on the discharge of

a fluorine-bearing anion, probably  $\text{AlF}_6'''$ . Addition of alumina apparently diverts fluorine attack from the anode material to itself, thus :

with regeneration of the aluminium fluoride.

The results of the experiments on the conductivity of molten cryolite are recorded in Table IV. The average value of all the determinations is 0.361 ohm per cm.<sup>2</sup> Taking the results for a temperature of 1025° C., the average becomes 0.352 ohm per cm.<sup>2</sup> These figures are distinctly lower than those of Arndt and Kalass,<sup>18</sup> whose average result for the same material at 1020° C. is 0.435 ohm per cm.<sup>2</sup> As previously indicated, the discrepancy is probably attributable to polarisation, particularly in view of the statements of these investigators regarding the difficulties experienced in balancing the electrical circuit.

### Conclusions.

The isolation of aluminium in the electrolytic cell can only be explained by postulating that either (a) the alumina is ionised in solution, probably giving rise to the ions  $\text{Al}^{+++}$  and  $\text{AlO}_3'''$ , and is primarily decomposed by the current, or (b) the cryolite is ionised, the alumina being unionised or ionised to a slight extent only. Numerous investigators have advanced evidence in favour of both theories, but in recent years the second has gained ground.

As alumina is added to cryolite, the conductivity of the melt falls. On the other hand, the conductivity is proportional to the sodium

fluoride content of the bath. It is difficult to believe, therefore, that the first theory can represent the true facts. The authors are inclined towards the view that the cryolite is the ionised solute carrying the current, an assumption in close accordance with the experimental observations.

The cryolite is probably completely ionised, thus :

There are other possibilities, however, and although the evidence cannot be regarded as conclusive without further confirmation, there is some indication from the current-voltage curves of the existence of two cations in molten cryolite.

On adding alumina to the bath, the oxide is decomposed at both electrodes. Considering firstly the anodic process, the chief reaction is :

the final product at the anode being oxygen or, in the presence of a carbon anode, a mixture of oxides of carbon. At the cathode we have :

Interaction of the secondary products of equations (1) and (2) regenerates the cryolite, thus :

Alternatively, the dissociation of the cryolite may give rise to the cation  $\text{Al}^{+++}$ , thus :

the sodium fluoride taking no active part in the electrolysis, a highly improbable suggestion. Apart from other considerations, the separation of sodium at the cathode during the operation of the technical process under certain conditions is by no means a rare occurrence.

Compared with the other ions in the melt, the sodium ion is relatively fast-moving, and tends to accumulate at the cathode where it is either discharged, the metallic sodium decomposing the alumina as in equation (2), or alternatively, there may be an exchange of charge between the sodium and aluminium ions, the latter proceeding from the slightly ionised alumina. Whichever view is adopted, the result is the same—the alumina plays the rôle of both anodic and cathodic depolariser, supplying aluminium at the cathode and regenerating aluminium fluoride at the anode.

### Summary.

(1) The decomposition voltages of cryolite and of a 16 per cent. alumina-cryolite mixture, electrolysed with platinum anodes at 1025° C., are 2.23 and 2.20 volts respectively.

(2) The same melts, electrolysed with graphite anodes at 1025° C., are decomposed at 1.7 and 1.5 volts respectively.

(3) The depolarisation never attains the theoretical maximum value, but varies probably with the state of reactivity of the anode material.

(4) The decomposition voltage of cryolite falls approximately linearly with increasing temperature.

(5) At 1025° C. the decomposition voltage-alumina content curve falls to a minimum at about 8 per cent. alumina. From 8.24 per cent. alumina there is a slight progressive increase in decomposition voltage.

(6) The conductivity of molten cryolite at  $1025^{\circ}$  C. is 0.352 ohm per cm.<sup>3</sup>

(7) In the aluminium cell the current is carried by the ionised cryolite. The alumina is either unionised or ionised to a slight extent only.

The authors are indebted to Mr. G. B. Brook, F.I.C., of the British Aluminium Co. Ltd., whose help and advice have greatly facilitated the progress of this work.

## THE BINDING OF GLACIAL PHOSPHORIC ACID BY THE PROTEINS OF WHEAT FLOUR.\*

BY L. W. SAMUEL † AND R. K. SCHOFIELD.

*Received 24th February, 1936.*

The property of coagulating water soluble proteins has long been used to distinguish glacial phosphoric acid from the other phosphoric and simple mineral acids. It was pointed out by one of us in an earlier paper<sup>1</sup> that, after adding an excess of this acid to a protein, an aliquot can readily be separated for back titration in order to determine the acid taken up by the protein. As it seemed possible that a determination of the acid binding capacity of the proteins in wheat flour might prove of practical utility, a number of measurements of this kind have been made.

### Glacial Phosphoric Acid.

The glacial phosphoric acid was procured from time to time in 100 gm. bottles of sticks or lumps. The solutions used (except where stated otherwise) were made by dissolving crushed fragments of the acid in cold distilled water at the rate of about 8 gm. per litre. The results of titrations of a freshly prepared solution with NaOH and  $\text{Ca}(\text{OH})_2$ , in which the change in  $p_H$  was followed with the aid of a glass electrode, is shown in Fig. 1. It is generally agreed that glacial phosphoric acid solutions contain not only monometaphosphoric acid— $\text{HPO}_3$ —but also polymers of general formula  $(\text{HPO}_3)_n$ . Thus, although there is only one titratable hydron to each phosphorus atom, a whole series of dissociation constants determine the form of the titration curve. These, however, fall into two main groups. A certain proportion of the hydrions having a relatively strong dissociation can be titrated with NaOH, using an indicator turning at about  $p_H$  4.5, whereas an indicator turning above  $p_H$  9 is needed to determine all the titratable hydrions. These end-points were first obtained by Sabatier,<sup>2</sup> who also observed that the titre to the second end-point increases with time, owing to hydrolysis, while the titre to the first remains unchanged. With solutions containing only 8 gm. per litre, the change in one hour at room temperature is, however, barely detectable.

\* This paper embodies with other matter the substance of a thesis by L. W. Samuel, approved for the degree of Ph.D. in the University of London.

† Hackett Research Student of the University of Western Australia.

<sup>2</sup> P. Sabatier, *Compt. Rend.*, 1888, **106**, 63; 1889, **108**, 738 and 804.

A titration curve for a freshly prepared solution of each batch of acid was obtained on first opening the bottle, using a quinhydrone electrode and NaOH (the glass electrode only becoming available towards the end of the investigation). These were all of the same general form as the upper curve in Fig. 1 (except that, owing to the limitations of quinhydrone, they could not be traced above  $p_H$  8), but were not identical in shape, as may be exemplified in the fact that the ratio of the titre to  $p_H$  4.5 to that at  $p_H$  8.0 varied from 0.61 to 0.70 for six bottles of stick acid, and was 0.56 for a bottle of lump acid. This variation is not surprising, as the proportions in which the constituent acids are present must depend on the exact conditions of preparation which are difficult to reproduce exactly.

FIG. 1.

#### Measurement of Acid Uptake.

The determination of acid uptake by back titration has special advantages when applied to a material such as wheat flour, which contains both soluble and insoluble buffering material. For, provided the  $p_H$  of the end-point of the back titration is the same as that of the material before it was mixed with the acid, the uptake measured is that of the precipitate only. From this it will be seen that neither end-point obtained with NaOH is suitable for wheat flour which is usually at about  $p_H$  6 in its natural state. With  $\text{Ca}(\text{OH})_2$  the second end-point is reached a little above  $p_H$  8 and can be obtained as low as  $p_H$  6 by adding calcium chloride. In practice a satisfactory end-point can be obtained simply with  $\text{Ca}(\text{OH})_2$  (nearly saturated—about  $N/22$ ) using thymol blue. This is because flour extracts have only a small buffering between  $p_H$  6 and 8.\*

\* This statement only applies strictly to high-grade flours.

In this way it was ascertained that interaction between the acid and the proteins in wheat flour is very rapid. 100 gm. of flour was added to 500 c.c. of acid, and the bottle containing the mixture was kept for some weeks and shaken occasionally. At suitable time intervals small amounts were removed and centrifuged, and 10 c.c. of the clear liquid was titrated with  $\text{Ca}(\text{OH})_2$  to thymol blue. Nitrogen was determined on each occasion on a further 20 c.c. Immediately after the first mixture had been made up, a second 100 gm. of flour was added to a further 500 c.c. of acid, and the mixture was shaken intermittently for 10 minutes. About 400 c.c. was then separated by centrifuging, bottled, and stored beside the first mixture. 10 c.c. samples of this liquid were withdrawn at intervals and titrated. 500 c.c. of the original acid was also kept and similarly titrated. It will be seen from Table I. that although all three titres increased with

time, owing to the hydrolysis of the metaphosphoric acid, there is for many hours no difference between the acid remaining in contact with the flour and that separated from it after 10 minutes' contact. This is most simply explained by supposing that the reaction was complete in 10 minutes, and that the acid bound by the flour protein undergoes practically no hydrolysis. It would be a very singular coincidence if, for many hours, slow hydrolysis of the bound acid exactly counteracted an increase in the amount bound. When a difference at length appears, an increase has occurred in the amount of nitrogen not precipitated which would itself affect the titre.

On the basis of this experiment, 10 minutes was adopted as the time of contact in measurements on a series of flours. In each case, 8 gm. of flour was shaken with 40 ml. of glacial phosphoric acid solution, centrifuged and filtered. 10 ml. of the filtrate was titrated with  $\text{Ca}(\text{OH})_2$  to thymol blue, as was also 10 ml. of the original acid. The uptake per 100 gm. of flour was calculated by multiplying the difference between the two titres by one hundred times the normality of the  $\text{Ca}(\text{OH})_2$  (determined on each lot) and divided by 2 (the grams of flour corresponding to the 10 ml. titrated).

#### The Uptake of Potassium Chloride, Hydrochloric Acid, Trichloroacetic Acid Compared with that of Glacial Phosphoric Acid—Water Binding.

This simple method of computation was only adopted after some preliminary experimentation. The first test was made by shaking up some flour with 0.1 N potassium chloride in order to discover whether the solution is concentrated through the "binding" of some water by the flour or diluted by a release of some of its air-dry moisture. A dilution was found,

but it was greater than could be accounted for by a release of all the air-dry moisture. The effect was even more pronounced with  $N/20$  solution. Thus some potassium chloride was taken up by the flour, and the experiment failed to give the information sought.

Some tests were then made by shaking up wheat starch with several acids at a series of concentrations. Of the whole flour, about 85 per cent. is starch which may, therefore, largely control the binding or release of water. Hydrochloric acid was found to be taken up in amounts which increased rapidly with increase in acid concentration above  $0.1N$ , but which approached a steady low value at lower concentrations. The limiting low value (of the order of  $0.01$  milliequivalents per gram of starch) presumably reveals a small capacity to combine with hydrions. The increase in uptake at higher concentrations, like the uptake of potassium chloride, must be ascribed to loose binding of the chloride ions. Similar large uptakes of hydrochloric acid by proteins from strong solutions have been reported by Jordan Lloyd and Mays,<sup>3</sup> Atkin and Douglas,<sup>4</sup> Hoffmann and Gortner,<sup>5</sup> and others. An essentially similar behaviour was found with trichloroacetic acid. We have pointed out<sup>6</sup> that this acid, being an effective protein precipitant even at  $0.1N$ , and at the same time a simple monobasic acid, may prove useful in determining the hydrion binding power of pure proteins.<sup>6</sup> Its uptake by starch places difficulties in the way of its use with flour.

The behaviour of glacial phosphoric acid is different. While solutions containing less than about  $8$  gm./litre ( $0.1N$  to the second end-point) are diluted a little on shaking with wheat starch, the strength of more concentrated solutions is slightly increased. The results can be accounted for by supposing that, for concentrations of this order of magnitude one gram of starch combines with a small amount of acid (roughly  $0.01$  milliequivalents) which does not vary much with the acid concentration, and at the same time binds about  $0.1$  gm. of water in addition to its air-dry moisture. These two processes acting together leave a  $0.1N$  solution practically unchanged in concentration.

#### The Capacity of Wheat Proteins to Bind Glacial Phosphoric Acid.

Thus it appears that provided the concentration of glacial phosphoric acid is about  $0.1N$  ( $8$  gm./litre), the starch added in the flour is without appreciable effect, and the change in the concentration is due to combination of acid with the proteins. If the flour proteins, when added to the acid, are not combined with either acid or base, the acid taken up will equal the acid binding capacity; otherwise a correction is necessary. The lowest  $p_H$  at which all anions could be washed out of flour was found by Loeb's<sup>7</sup> ferrocyanide method to be close to  $p_H$  6. The amount of acid or alkali needed to bring each flour to  $p_H$  6 was therefore determined. It usually lay between  $+0.2$  and  $-0.2$  milliequivalents per 100 grams of flour, which is a very small fraction of the acid uptake which averaged about 8.

As the amount of protein present may be taken as substantially proportional to the nitrogen content, the acid binding capacity (the uptake corrected to  $p_H$  6) is plotted in Fig. 2 against the nitrogen precipitated

<sup>5</sup> W. A. Hoffman and R. A. Gortner, *Colloid Symp. Mon.*, 1925, 2, 209.

<sup>6</sup> R. K. Schofield and L. W. Samuel, *Nature*, 1934, 134, 665.

<sup>7</sup> A. D. Ritchie has drawn our attention to a physiological investigation in which he titrated trichloroacetic acid extracts of proteins (*J. Physiol.*, 1929, 68, 295). The purpose was not, however, to determine the acid binding power of the proteins.

<sup>8</sup> J. Loeb, *Proteins and the Theory of Colloidal Behaviour*, McGraw Hill & Co., 1922, p. 30.

from one gram (*i.e.* the total nitrogen in 1 gm. less the amount found in 5 ml. of the extract which varied from 1.2 to 3.5 per cent. of the total). While there is a general tendency for the acid binding capacity to be greater the greater the amount of protein present, the flours with high nitrogen content on the whole bound less acid per unit weight of protein. At the same time, the variation in the acid binding of flours with the same nitrogen content is far outside the errors of titration (equivalent to 0.1 milliequivalents per 100 grams of flour at most). It has long been recognised that while the nitrogen content is a general indication of certain properties of a flour, there is considerable variation between flours with the same protein content. It is suggestive that the flour with 1.9 per cent. of nitrogen and an acid uptake of only 6.65 milliequivalents per cent. had a decidedly smaller water absorption than would have been expected simply from its nitrogen content. It is hoped that when better methods are

FIG. 2.

available for specifying quantitatively the physical properties of flour doughs such as those which, following the work of Schofield and Scott Blair<sup>a</sup> are being worked out jointly in this laboratory, and in that of the Research Association of British Flour Millers, it will be possible to decide whether a determination of acid binding capacity is of technical value.

#### The Selective Action of Proteins on the Constituents of Glacial Phosphoric Acid.

In the meantime it appeared of interest to study more closely the interaction between glacial phosphoric acid and proteins. To this end, the water soluble constituents were removed from a flour by repeated washing, and the insoluble residue was shaken with 0.1N glacial phosphoric acid. In this case there is no restriction on the  $p_H$  to which the back titration should be taken. Titration curves were therefore obtained for the acid

<sup>a</sup> R. K. Schofield and G. W. Scott Blair, *Proc. Roy. Soc.*, 1932, 138A, 707; 1933, 139, 557 and 141, 72.

before and after contact, with the aid of a quinhydrone electrode, using NaOH as alkali. A comparison of these two curves revealed differences, not only in the absolute magnitudes of the titres to the same  $p_H$ , but also showed that whereas for the original acid the titre to  $p_H$  4.5 was 0.623 of the titre to  $p_H$  8, the corresponding ratio after contact with washed flour was 0.601. The washed flour was very wet when added to the acid, but dilution from this cause would not have affected the *ratio* of the titres. It thus appeared that flour proteins do not bind the various  $(HPO_3)$  units in the proportion in which they exist in the original glacial phosphoric acid solution, but remove relatively more of those that buffer below  $p_H$  4.5.

In a further study of this selective action, experiments were carried out with gluten (the total water insoluble wheat protein) and glutenin (the residue of gluten insoluble in 70 per cent. alcohol) which were both procured from commercial sources in a powdered air-dry condition. A sample of gliadin (the fraction of gluten soluble in 70 per cent. alcohol) was prepared from some of the gluten. For our immediate purpose it was sufficient, instead of tracing the whole curve electrometrically, to determine the titres to the two inflection points with the aid of indicators. The first inflection at  $p_H$  4.5 is readily detected by bromo-cresol green. For the second inflection use was made of phenol-phthalein mixed with enough methyl red and bromo-thymol blue to give a neutral grey at  $p_H$  9.5, the half-colour point. This is perhaps a little on the acid side of the actual inflection, but the curve is, nevertheless, steep enough at this  $p_H$  for a sensitivity to be obtained of one drop in a total titre of 20-25 c.c. Some typical results are shown in Table II. Before discussing the differences between the three

TABLE II.—ACID UPTAKE OF GLUTEN, GLUTENIN AND GLIADIN IN MILLI-EQUIVALENTS PER GRAM OF NITROGEN.

materials, it is desired to draw attention to the discrepancies between the first two columns. These refer to the same material, but the measurements were made on different days with acid from different bottles. The difference between the two solutions of acid is exemplified in the figures of row (1). The discrepancies, particularly those in row (2), are greater than can be accounted for by titrational errors. Although the extreme values for eight lime titrations row (5), carried out at intervals over a period of several months—namely 4.17 and 4.34—only differ by 5 per cent., which is small in comparison with the variation in the uptake per gram of nitrogen shown by the flours of Fig. 2 (extreme values 3.52 and 4.82), it would probably be as well in future measurements with glacial phosphoric acid on flours to include a measurement on a stock gluten amongst those for each acid solution in order to relate more exactly measurements made with different solutions.

This source of error does not arise in comparing the two middle columns of the table, one for the gluten and the other for the glutenin, as the same

acid solution was used with both. It will be seen that the ratios given in row (4) are decidedly different both from each other and from the ratio in row (1). Now the figures in row (3) (or row (5) for they are substantially equivalent) give the *total* number of  $\text{HPO}_4$  units taken up per gram of nitrogen. The figures in row (2) only give the number of those taken up which have a relatively strong hydron dissociation. The ratio given in row (4) is therefore the proportion of the  $\text{HPO}_4$  units taken up which have a strong dissociation, while the ratio in row (1) is the proportion in the original acid having strong dissociation. The conclusion derived from the experiment with the washed flour is thus confirmed, and in addition it becomes apparent the proteins differ in the degree of their selective action. The experiment recorded in the last column shows an extreme selectivity on the part of the gliadin which took up almost exclusively  $\text{HPO}_4$  units having a strong dissociation.

It was argued in the paper already referred to,<sup>1</sup> that the precipitating action of glacial phosphoric acid indicates the presence of an anion which becomes firmly bound to basic nitrogen groups by some force over and above mere electrostatic attraction. Reasons were given for thinking that not all  $\text{HPO}_4$  units would be capable of this firm binding and, further, that all possible  $(\text{HPO}_4)_n$  molecules can be divided into two groups according as they have or have not an active  $\text{HPO}_4$  unit in their structure.

From the differences in the behaviour of the materials investigated, it now appears that the basic groups of proteins can also be divided into categories according to their selective action on the various metaphosphoric acids. To explain the results so far obtained, it is sufficient to suppose that the gliadin contained a large proportion of groups having a specific attraction for the "active" metaphosphoric acids, while glutenin, though it may have contained a fair proportion of these, had a considerable number that were non-specific in their action. In this connection it is interesting to note that glutenin is reported to contain considerably more arginine in its make-up than gliadin. The suggestion that the guanidine nucleus is prominent among the non-specific groups is not unreasonable on general grounds, seeing that its reactions are decidedly different from those of other basic nitrogen groups. This idea receives support from some experiments with edestin. These are not reported here in detail, as we had insufficient material for a complete examination, but the measurement showed that the edestin was less selective than the glutenin. It is reported to contain more arginine.

It should be emphasised, however, that it cannot strictly be argued from the marked differences in selectivity found with these particular samples that all gliadins and glutenins are similarly differentiated. Thus, although the figures for the gluten fall between those for the gliadin and the glutenin, as would be expected, it must be borne in mind that the acid binding capacity of the flours varied from 3.52 to 4.82 milliequivalents per gram of nitrogen. Comparing these figures with those in row (5) of Table II, it will be seen that they nearly bridge the gap between those for the gliadin and the glutenin. It is very improbable that the gliadin/glutenin ratio varies between the limits that would be required if the figures given held good for all gliadins and glutenins, and much more likely that their acid binding capacity is subject to some variation according to their source. As, however, the gliadin was prepared from the gluten, it is probable that the figures for gliadin and glutenin prepared from the same gluten will be found to bear to one another the general relationship shown in Table III.

Before discussing the figures in row (6) of Table II., mention should be made of experiments carried out with glacial phosphoric acid at other concentrations besides 0.1*N*. In dealing with separated proteins, this concentration has not the special advantage noted in the case of flour, but is nevertheless convenient, since stronger solutions hydrolyse more rapidly, while larger volumes of liquid must be used to get equivalent accuracy with weaker solutions. The experiments summarised in Table III. show

TABLE III.—UPTAKE OF GLACIAL PHOSPHORIC ACID BY GLUTEN FROM SOLUTIONS OF DIFFERENT CONCENTRATIONS IN MILLIEQUIVALENTS PER GRAM OF NITROGEN.

Concentration of acid (N)	0.02	0.04	0.10	0.20	0.40	1.0
Weight of gluten (gm.)	3	3	3	6	6	9
Volume of acid added (m.e.)	500	250	100	100	50	30
Volume titrated (ml.)	100	50	20	10	5	2
Uptake from titre to $p_H$ 4.5 with NaOH	3.60	3.59	3.93	3.98	4.04	3.90
Uptake from titre to $p_H$ 9.5 with NaOH	4.08	4.10	4.31	4.38	4.41	4.22

how little the uptake depends on the strength of the acid used, though there is a slight increase with increasing concentrations up to 0.4N. Thereafter it falls a little, presumably because any real increase there may have been in the uptake of acid was more than offset by the effect of water binding. At 0.1N water binding presumably made only about one-tenth the apparent negative contribution to the measured uptake, and so can be neglected.

In the experiments of Table II., one gram of protein was added to 40 ml. of 0.1N acid, while in those of Table III., 1.2 gram was added per 40 ml., and proportionally more or less according to the strength of the acid, so that approximately the same fraction of the acid was removed in each case. Table IV. shows how the uptake per gram of nitrogen varies

TABLE IV.—UPTAKE OF GLACIAL PHOSPHORIC ACID BY DIFFERENT WEIGHTS OF GLUTEN ADDED TO 0.1N ACID.

Weight of gluten added to 60 ml. acid	1.0	1.5	2.0	3.0	4.0
Uptake per gram N from titre to $p_H$ 4.5 NaOH	3.86	3.89	3.86	3.72	3.68
Uptake per gram N from titre to $p_H$ 9.5 NaOH	4.39	4.34	4.30	4.15	4.03

with the weight of gluten added to 60 ml. of 0.1N acid. It will be seen that as far as 2 gm. in 60 ml. (i.e. 1.33 gm. in 40 ml.) the variation in the measured uptake is within experimental error. At this point the titre to  $p_H$  4.5 has been reduced about one-third, and that to  $p_H$  9.5 by one-quarter, 8 gm. of even the most reactive flour added to 40 ml. of 0.1N acid would not over-pass this limit.

The figures in row (6) of Table II. refer to determinations made with trichloroacetic acid. As already noted, this acid is taken up by proteins in ever-increasing amounts, with rise in concentration above about 0.1N, but from 0.05N down to such low concentrations that precipitation is no longer complete (which varies with the protein) the uptake is substantially constant. This being a very strongly dissociated monobasic acid, it seems reasonable to assume that all the hydrions removed from these dilute solutions combine directly with the protein, and that a measure is obtained in this way of the true hydrion binding power of the protein. The differences between corresponding figures in rows (2) and (3) are a measure of the weakly dissociating hydrions removed from solution in combination with polybasic anions, one or more hydrions of which, being strongly dissociating, have combined with the protein. The differences between row (3) and row (6) further show that some fairly strongly dissociating hydrions are also removed from the solution, in addition to those combined directly with the proteins which are presumably the same in amount whatever acid is used, provided the  $p_H$  is low enough. Whereas the glutenin took up more polybasic anions with weakly dissociating hydrions attached, the gluten took up more with additional strongly dissociating hydrions—a

further indication of differential selective action. It is proposed to discuss these and other observations in their bearing on the molecular structure of the metaphosphoric acids more fully in another paper.

A comparison of row (5) with row (6) shows that for the gluten the number of hydrions, both weakly and strongly dissociating, taken up in association with polybasic metaphosphate anions is about one-quarter of the total, the remaining three-quarters being combined directly with the proteins. From the number of hydrions directly combined, it is easy to calculate that only one in every twenty-two nitrogen atoms in the gluten was able to co-ordinate a hydrion. It should be added that this statement is based on the additional information that the  $p_H$  of the gluten was close to  $p_H$  6, which was found by Loeb's ferrocyanide method to be the lowest  $p_H$  at which the material could be freed of anions. The acid uptake was thus substantially the acid binding power. Thus, when the acid used for the measurement is glacial phosphoric, the acid bound is some 30 per cent. in excess of the hydrions bound direct to the protein.

#### The $p_H$ of the Uncombined Proteins.

Measurements by Loeb's method on the gliadin and glutenin indicated that here also the figures in the table are substantially the acid binding capacities. The minimum  $p_H$  for washing out anions was observed to be  $p_H$  5.5 for the glutenin, and  $p_H$  6.85 for the gliadin. The value for glutenin is in agreement with those previously reported by Kondo<sup>9</sup> and his co-workers. That for gliadin is close to the value  $p_H$  6.5 given by Csonka, Murphy and Jones,<sup>10</sup> but quite different from  $p_H$  5.1 recently reported by Kemp and Rideal.<sup>11</sup> For our purpose we need the  $p_H$  at which the protein is uncombined, and Loeb's method is a very direct way of determining this. This  $p_H$  has a definite value, even for a mixture of proteins which separately give different  $p_H$ 's for no combination, for, as Bungenberg de Jong<sup>12</sup> has pointed out, the proteins may be regarded as combined with each other between these  $p_H$  values. From the standpoint of the zwitterion theory, this combination merely means a balancing of the electric changes of oppositely charged proteins without the necessity for the presence of other ions. It has generally been assumed that a material is isoelectric (*i.e.* it does not exhibit cataphoretic movement) when it is at the  $p_H$  at which it can be washed free of extraneous ions.

#### Summary.

Making use of the fact that glacial phosphoric acid is a protein precipitant, measurements have been made of the capacity of the proteins of wheat flour to bind this acid by shaking them up with an excess of the acid and determining the amount remaining in solution by back titration on an aliquot.

Solutions of potassium chloride, hydrochloric acid and trichloroacetic acid are slightly diluted by shaking with wheat starch, but there is no appreciable change in the concentration of a solution containing about 8 gm. of glacial phosphoric acid per litre, owing to the balancing of a very small uptake of acid by a "binding" of some water by the starch. The

<sup>11</sup> I. Kemp and E. K. Rideal, *Proc. Roy. Soc.*, 1934, 147A, 11. In a paper shortly appearing Kemp states that the gliadin used by Kemp and Rideal had been denatured by long contact with alcohol, and gives a value of  $p_H$  5.92  $\pm$  0.005 for the isoelectric point of the native protein which is in substantial agreement with ours.

<sup>12</sup> H. L. Bungenberg de Jong, *Trans. Faraday Soc.*, 1932, 28, 798.

concentration change caused by adding flour is therefore due to acid taken up by the protein.

The capacity of thirty-seven flours to bind glacial phosphoric acid varied from 6.7 to 10.1 milliequivalents per 100 gm. of flour. The uptake tended to be greater for the flours of higher nitrogen content, but the acid bound per gram of nitrogen varied from 3.52 to 4.82.

Although electrometric titrations revealed differences in the proportions of the constituent metaphosphoric acids in different batches of glacial phosphoric acid, determinations of the binding capacity of a gluten with eight different solutions gave a variation of only 5 per cent. between the highest and lowest values.

The uptake per gram of a gluten varied only slightly with the concentration of the acid between 0.02 and 1.0 normal, and was independent of the amount of gluten added, provided not more than a quarter of the acid was removed from the solution. In confirmation of a theory of the molecular structure of the metaphosphoric acids, put forward in an earlier paper, it has been found that protein removes certain metaphosphate ions from solution in preference to others. It has further been found that different proteins are selective to different degrees, showing that their basic groups can be differentiated as regards their action on glacial phosphoric acid.

Reasons are given for thinking that the uptake of trichloroacetic acid by gluten from a 0.5*N* solution is a measure of its hydrion binding capacity; if so, the additional titratable acid bound (roughly 30 per cent.) when glacial phosphoric acid is used, must be in the form of hydrions associated with polybasic anions.

The lowest  $p_H$  at which the materials could be washed free of anions (the isoelectric point) was found by Loeb's ferrocyanide method to be: the gluten —  $p_H$  6.1, the gliadin —  $p_H$  6.85, the glutenin —  $p_H$  5.5, and one of the flours  $p_H$  5.95. The  $p_H$  values were in each case close to those of the materials as procured, and a correction of a few per cent. only had to be applied to the acid uptake to obtain the acid binding capacity.

Our thanks are due to Dr. E. A. Fisher and Dr. P. Halton of the Research Association of British Flour Millers for supplying the flours used in this investigation and for giving information regarding them.

## THE TEMPERATURE COEFFICIENT OF THE SOLUBILITY OF HYDROGEN IN ORGANIC SOLVENTS.

BY E. B. MAXTED AND C. H. MOON.

*Received 20th February, 1936.*

While the variation with temperature of the solubility of hydrogen in the organic solvents commonly used in catalytic hydrogenation is of considerable importance in the analysis of the factors which control the temperature coefficient of hydrogenation reactions in liquid systems, little has been published on the magnitude and direction of this variation for the common hydrogenation solvents, *e.g.* acetic acid and ethyl alcohol, over a reasonably extensive range of temperature.

Earlier work <sup>1</sup> indicates that, in general, the variation of solubility with temperature is positive; but (save for benzene, which was studied by Horiuti, and alcohol, for which solubility values between 0° and 19° were measured by Timojew) measurements are available, for the solvents now investigated, only at 20° and 25°.

In the present work, solubility determinations have been made for acetic acid, ethyl alcohol, ethyl acetate, chloroform and benzene, over a wide temperature range. The data obtained are expressed in the form of the Bunsen solubility coefficient, namely as the volume of hydrogen, reduced to N.T.P., which, at the temperature of the measurement, is dissolved by one volume of the solvent when the partial pressure of the gas is 760 mm. This coefficient,  $\alpha$ , bears a relationship to the Ostwald coefficient, used by Just, Christoff and Horiuti, of the form:

$$\alpha = \frac{273}{T} \gamma$$

in which  $T$  is the absolute temperature and  $\gamma$  the Ostwald coefficient, *i.e.* the ratio of the concentration of the hydrogen in the liquid phase to its concentration in the gas phase. Each of these coefficients requires a knowledge, firstly, of the coefficient of dilatation of the liquid studied, (in the case of a gas of low solubility, dilatation due to the dissolved gas is negligible) and, secondly, of the vapour pressure of the solvent at the temperature of the determination. The operation of the Henry-Dalton law is assumed, since, as Horiuti has pointed out, any deviations from this are likely to be small under the conditions of the measurement and data are not available for applying this possible small correction.

FIG. 1.

### Experimental.

A considerable amount of preliminary work was carried out in order to determine suitable apparatus and general technique. The apparatus employed by Just consisted of an absorption vessel, which was connected with a gas-measuring system and shaken. Horiuti used a magnetically operated stirrer in place

of shaking the absorption vessel.

At the beginning of the present work, Horiuti's apparatus, with the exception of a small modification in the gas burette, was constructed and in general, was found to work very well; there appeared to be room for improvement only in minor points. The slight overheating of the liquid in the absorption pipette by the coil of the electromagnet operating the stirrer was minimised by making the coil a self-contained immersed unit of sufficient diameter to allow an annulus of the thermostatic liquid to interrupt direct contact between this coil and the glass wall of the absorption

<sup>1</sup> W. Timojew, *Z. physikal. Chem.*, 1890, 6, 141; G. Just, *ibid.*, 1901, 37, 342; A. Christoff, *ibid.*, 1917, 79, 456; J. Horiuti, *Inst. Chem. Physic. Research, Tokyo*, 1931, 17, 125.

pipette. This modification is shown in Fig. 1, in which A is the magnetically operated stirrer which is caused to rise and fall by interruption of the current flowing through the coil, B. The stirrer was of glass, of annular form, sealed over a short length of soft iron tubing and was provided with external glass fins, as shown. An internal thermometer pocket, C, acted as a vertical axis and guide for the stirrer. The diagram also shows the general arrangement adopted for degassing,<sup>2</sup> the liquid being boiled under reduced pressure in the flask, D. The portion of the degassed liquid taken for the solubility measurement was sealed from the remainder by a mercury cushion, E; and its volume was determined by weighing. Some measurements carried out with this apparatus are included in the section dealing with solubility in acetic acid.

For efficient stirring, however, including the provision of conditions such that the surface of the liquid in the pipette was broken by the stirrer, the free gas space above the solvent had, for mechanical reasons, necessarily to be of a greater volume than is conducive to accuracy in measuring the gas absorption: otherwise, with less vigorous stirring, the time of attain-

FIG. 2.

ment of equilibrium became rather prolonged. As an alternative to magnetic stirring, agitation of the absorption vessel itself, as in Just's method, was tried, the vessel being connected with the gas burette by a capillary connection. This avoided local overheating; but there is a tendency towards the formation of liquid threads in the connecting capillary, with consequent obstruction of accurate reading.

The apparatus finally adopted is illustrated in Fig. 2. The gas space above the solvent was reduced to a minimum by employing a solution vessel of the form shown at A. This vessel, which was immersed in a thermostat, contained, in addition to the solvent, a small quantity of mercury, B, and was rocked so that the mercury and the gas bubble, C, moved along the tube in opposite directions. This secured intimate contact of the gas with the whole of the previously degassed liquid, and led to a relatively rapid attainment of equilibrium.

The absorption vessel was connected by a long glass capillary link, D, approximately 1 metre in length, to a gas-measuring system, E, which was immersed in a glass-fronted tank maintained at a constant temperature.

<sup>2</sup> Cf. Horiuti, *loc. cit.*<sup>1</sup>.

The smaller of the gas burettes was graduated in hundredths of a cubic centimetre.

The various solvents were already available in a high state of purity; and purified electrolytic hydrogen was used. Further purification by sorption in, and desorption from, palladium did not cause any measurable change in the observed solubility values.

In order to carry out a measurement, the absorption vessel was detached by cutting the connecting tube at the point, F. A small quantity of clean mercury was introduced, and the vessel was filled with solvent with the exception of the space C. The free absorption vessel, containing the solvent, was now immersed in warm water, in such a position that the gas space, C,

FIG. 3.

was uppermost, and degassing was carried out by prolonged boiling *in vacuo*. Since the obtaining of concordant maximum values for the solubility depends on the completeness of this degassing process, great care was taken with this stage. The elimination of dissolved gas was accelerated by periodically closing the tap and vigorously shaking the absorption vessel: further, the shape of the vessel was, in itself, conducive to the rapid and complete freeing of the liquid from dissolved gas, since the boiling took place from the bottom of, and throughout, the liquid, by reason of the small area available for surface evaporation; and the bubbles of solvent vapour thus traversed and scavenged the whole of the bulk of the liquid. The replacement of tap grease by, for instance, the

mixture of phosphoric acid and caramelised glucose used by Horiuti, was found to be unnecessary if the tap was re-greased for each measurement.

The absorption vessel was now re-connected by fusion to the remainder of the apparatus and allowed to attain the temperature of the thermostat. The flexible capillary link, D, was next evacuated with a Hyvac pump, then filled with hydrogen from the large burette and re-evacuated, evacuation and filling being carried out from opposite ends of the link in order to avoid a cushion effect. Finally, the gas-measuring system was placed in connection with the degassed liquid. In the absence of rocking, solution was very slow—of the order of 0.01 c.c. per minute—and the position of the zero point could thus be determined accurately. The rocking mechanism was now started, and the absorption followed by means of the smaller burette.

**Solubility of Hydrogen in Acetic Acid.**—The solubility of hydrogen in this solvent was determined in three independent types of apparatus, namely by the rocking pipette method, as described above, in apparatus provided with a magnetic stirrer of the Horiuti type, and in a mechanically shaken absorption pipette. The results obtained by these three methods are summarised in Table I.

The concordance of the results obtained in Series *a* and *b*, which is most easily seen by reference to the collective graph, may be noted. The figures are, moreover, in good agreement with Just's previous determinations,  $\alpha_{10} = 0.0575$  and  $\alpha_{25} = 0.0580$ . The values obtained in the apparatus provided with a magnetic stirrer were slightly lower than the above, probably for the reasons already discussed; and it is considered that the variation of solubility with temperature is most accurately given by the closely agreeing results of Series *a* and *b*.

**Solubility in Ethyl Alcohol.**—For this, and for the remaining solvents, the rocking pipette method was used throughout. The experimental results for the temperature range 0–50° are also contained in Table I.

Just's values  $\alpha_{10} = 0.0804$  and  $\alpha_{25} = 0.0819$  are slightly higher than the above figures; but the alcohol used by Just is stated to have been of 98.5 per cent. purity, whereas, in the present work, a pure specimen was employed.

**Solubility in Ethyl Acetate.**—Data relative to this are also contained in Table I. As before, previous data, due to Just, are only available for 20° and 25°. Just's value of  $\alpha$  for the latter temperature (0.0780)

falls almost exactly on the above curve. His value for 20° (0.0734) is slightly lower.

**Solubility in Chloroform.**—The values obtained are given in Table I.

**Solubility in Benzene.**—In this case, previous data, due to Horiuti, are available for comparison, in addition to Just's figures for 20° and 25°.

If the results in Table I. are compared with Horiuti's figures and with those of Just, converted in each case into the form of the Bunsen coefficient, it will be seen that there is almost complete agreement with Horiuti's values but that Just's

figures are slightly higher. The comparison is shown in Table II.

### Summary.

The solubility of hydrogen in acetic acid, ethyl alcohol, ethyl acetate, chloroform and benzene has been determined over various ranges of temperature lying between 0° and 75°. In each case a positive temperature coefficient was observed.

The results have been examined critically in connection with the known solubility values at 20° and 25° and, in the case of benzene—for which solubility measurements have already been made up to about 60°—over a wider range. In general, where checking values are available, there is good agreement.

University of Bristol.*

## THE DISSOCIATION CONSTANTS OF SOME POLYBASIC ACIDS.—PART II.

BY W. R. MAXWELL AND J. R. PARTINGTON.

*Received 25th February, 1936.*

The present communication deals with the acids :

These acids complete the series of acids formed by substituting hydrogen atoms in benzene by carboxyl groups, the other members having been, with the exception of terephthalic acid, described in Part I.<sup>1</sup> It has not been possible to determine the constants of this acid owing to its extremely slight solubility. The experimental method and the method of calculation used were the same as described in Part I., but it should be pointed out that the various expressions given for "u" on page 925 of Part I. are really expressions for "—u" and should therefore be multiplied by —1. This correction does not affect the validity of any of the formulæ or results given as expressions of the correct sign were actually used.

### Preparation of Acids.

**Trimellitic Acid.**—Pure pseudo-cumene (B-pt. 169° C., 760 mm.) was first prepared from Kahlbaum's pseudo-cumene ("pure" B-pt., 160–170° C.) by conversion into the sulphonic acid, recrystallisation of the latter, and subsequent hydrolysis with superheated steam.<sup>2</sup> This was then oxidised with alkaline permanganate,<sup>3</sup> and the acid obtained through the barium salt. It was recrystallised several times from conductivity water. M.-pt., 238° C.

**Trimesic Acid** was prepared by oxidation of mesitylene with alkaline permanganate.<sup>4</sup> It was isolated through the barium salt and recrystallised several times from conductivity water. M.-pt., 368° C.

**Mellophanic Acid.**—Owing to some confusion in the literature as to the structure and melting-point of this substance it was thought desirable to prepare it by two different methods :

<sup>1</sup> Maxwell and Partington, *Trans. Faraday Soc.*, 1935, 31, 922.

<sup>2</sup> Jacobsen, *Lieb. Ann.*, 1877, 184, 199. Schultze, *Ber.*, 1909, 42, 3603.

<sup>3</sup> Schultze, *Lieb. Ann.*, 1908, 359, 143.

<sup>4</sup> Ullmann and Uzbachian, *Ber.*, 1903, 36, 1799.

FIG. 1.

FIG. 3.

FIG. 4.

(a) Pentamethyl benzene was caused to undergo the Jacobsen reaction with concentrated sulphuric acid whereby hexamethyl benzene and 1 : 2 : 3 : 4 tetramethyl benzene sulphonic acid were obtained.<sup>5</sup> The latter compound was isolated as the sodium salt and from this by treatment with concentrated sulphuric acid and superheated steam 1 : 2 : 3 : 4 tetramethyl benzene was obtained which was oxidised to the corresponding acid with alkaline permanganate.<sup>6</sup> The acid was isolated through the barium salt and recrystallised several times from conductivity water. M.-pt., 244° C.

(b) 4 : 7-Dimethyl-2 : 2-diethylindan-1 : 3-dione was first prepared<sup>7</sup> by condensing diethyl malonyl chloride with *p*-xylene in carbon disulphide solution in the presence of aluminium chloride. This was then oxidised with nitric acid in sealed tubes at 140° C. The benzene 1 : 2 : 3 : 4 tetra-

FIG. 5.

carboxylic acid isolated from the product was crystallised several times from concentrated nitric acid, heated in a vacuum for 8 hours at 160° C. over KOH, and finally recrystallised from conductivity water. M.-pt., 244° C.

**Prehnitic Acid.**—Mesitylene carboxylic acid<sup>8</sup> was first prepared from bromomesitylene by Grignard's reaction, treatment with  $\text{CO}_2$ , and subsequent decomposition with ice and hydrochloric acid. This was then dissolved in sodium carbonate solution and oxidised to prehnitic acid with alkaline permanganate on the water bath, the oxidation being complete

<sup>5</sup> Smith and Lux, *J. Amer. Chem. Soc.*, 1929, 51, 2997.

<sup>6</sup> Töhl, *Ber.*, 1888, 21, 907.

<sup>7</sup> Freund and Fleischer, *Lieb. Ann.*, 1915, 411, 14.

<sup>8</sup> Bamford and Simonsen, *J. Chem. Soc.*, 1910, 97, 1904.

after about thirty hours. The acid was isolated through the barium salt and recrystallised several times from conductivity water. M.-pt., 263-266° C. Oxidation with dilute nitric acid in sealed tubes at 170-180° C.\* gave a product which was difficult to purify.

**Pyromellitic Acid.**—Acetyl *pseudo*-cumene was first prepared from *pseudo*-cumene and acetyl chloride by the Friedel-Craft's reaction, and this was then oxidised first to durylic acid with sodium hypobromite,<sup>8</sup> and then to pyromellitic acid with alkaline permanganate. The acid was isolated through the barium salt and recrystallised several times from conductivity water. M.-pt., 276° C.

Acids containing water of crystallisation were dehydrated by heating at 110° C. in a vacuum over phosphorus pentoxide before weighing out.

#### Remarks on the Titrations.

The titration of solutions of mellophanic acid prepared by both methods and at the same concentration of both acid and alkali gave the same results, thus showing them to be identical. Trimesic acid was titrated at one

concentration only, owing to the fact that, for solutions of higher concentration than that given, appreciable salting out of the acid occurred at the junction with the potassium chloride solution in the bridge, and solutions of lower concentration were not likely to give reproducible results. The curves obtained by plotting  $\Delta paH/\Delta$  ml. alkali against ml. alkali show a number of "humps" corresponding to the basicity of the acid except in the case of trimesic acid, the three constants of which are not greatly different in magnitude, and hence a more or less smooth curve results. The values of the constants calculated are given in Table I. (1-10), and the data necessary for their calculation in Table II. (I. to X.). The volume of acid solution used for each titration was 20.05 ml. in cases 1 and 2 and 20.02 ml. in cases 3-10.

### Discussion of Results.

The complete consequences which follow from the above results have not yet been worked out, but it appears that the promoting effect of unionised carboxyl groups is not, as had seemed possible from the results in Part I., simply a function of their number and distance apart. Thus,  $k_1$  for benzene 1 : 2 : 4 tricarboxylic acid is about twice as great as  $k_1$  for benzene 1 : 2 : 3 tricarboxylic acid in which the groups are closer together, and similarly:  $k_1$  for pyromellitic acid is greater than  $k_1$  for mellophanic acid where again the groups are closer together.

The values of the last dissociation constants are, however, in agreement with the hypothesis that the negative charge or charges on a dissociating ion produce an inhibiting effect which is a simple function of their number and distance from the dissociating carboxyl group. Two small deviations from this rule which arise when  $k_4$  for prehnitic acid is compared with  $k_3$  for hemi-mellitic acid, and  $k_3$  for trimellitic acid is compared with  $k_2$  for phthalic acid, are probably accounted for by deviations from the laws of ideal electrolytes. It should be pointed out that in drawing conclusions from the above results, and those in Part I., it must be remembered that in all except a few cases where the carboxyls in the dissociating molecule or ion occupy equivalent positions, the constants do not represent a simple equilibrium. Thus, for example, the first stage of ionisation of trimesic acid, whose carboxyls occupy equivalent positions, can occur in only one way (I.), but that of hemi-mellitic acid, in which the carboxyls are not all in equivalent positions, can occur in two ways (II.a and II.b), so that  $k_1$  for the latter acid involves two different constants:

I.

II.a

II.b

It is hoped to discuss the results in more detail in a later paper.

The authors wish to thank the Chemical Society for a grant which has helped to defray the cost of the research.

## THE SYSTEM LAURIC ACID—SODIUM HYDROXIDE—WATER.

BY C. R. BURY AND R. D. J. OWENS.

*Received 26th February, 1936.*

This is a continuation of previous work<sup>1</sup> on systems of the type  $XOH-MOH-H_2O$  (where  $XOH$  is a fatty acid, and  $M$  a metal), the object being to trace the changes that occur as the number of carbon atoms in the fatty acid changes, and as the nature of the metal is changed. Data for the system lauric acid—sodium hydroxide—water at 25° C. are presented here.

### Experimental.

The general method of procedure was to mix lauric acid and a solution of sodium hydroxide of suitable concentration in a resistance glass tube, which was evacuated to avoid frothing, and sealed off. The tube was heated to 100° to ensure complete interaction of its contents, a homogeneous solution being generally obtained, and then shaken in a thermostat at 25° for periods up to eight weeks. The contents of the tube were filtered through a sintered glass filter-funnel, the operation being performed in the thermostat and in an atmosphere of nitrogen, and the liquid and moist solid analysed.

Modifications of this procedure were frequently necessary. Neutral or slightly alkaline solutions set on cooling to an opaque gel—the wet curd—that shows numerous hair-like strands of fibre—the curd—under the microscope. The wet curd is unsuitable for phase rule work as it can only be separated with difficulty into solution and moist solid. This difficulty was obviated by a process of artificial ageing. The wet curd was alternately cooled in tap water and heated in the thermostat for periods up to a month, being frequently broken up by vigorous shaking. In this ageing process it is essential that the mixture should never be heated above the temperature at which it is desired to establish equilibrium. As a result of this treatment the gel undergoes syneresis and the fibre strands become relatively short and collect in clumps, but do not appear to be otherwise,

<sup>1</sup> *Trans. Faraday Soc.*, 1935, **31**, 480.

changed, and can now readily be separated from the solution by filtration. Before this, however, the mixtures were shaken in the thermostat to ensure the establishment of equilibrium.

Lauric acid does not react completely with strong alkali even on heating to  $100^\circ$  and after continuous shaking for long periods. Apparently sodium laurate is so insoluble in strong alkali that it can act as a protective coating to the underlying acid. In studying equilibria involving strong alkali it is necessary to dissolve the lauric acid in weak alkali and then to add more sodium hydroxide.

Mixtures composed of dilute soap solutions with slight excess acid form colloidal suspensions of acid soap. The colloidal particles do not settle out completely on long standing, nor can they be separated from the mother liquor by any ordinary filter. Ultrafiltration had to be employed for these mixtures, a collodion membrane being used.

FIG. 1.

Mixtures composed of more concentrated soap solutions with excess acid separate on cooling into two liquid layers, a less dense layer of anisotropic liquid (liquid crystalline phase) and a denser layer of isotropic liquid (ordinary solution phase). Shaking forms an emulsion of the liquid crystalline phase in the ordinary solution phase which only settles out with extreme slowness. Pure samples of the lower layer can be obtained with ease, but it is impossible to get pure samples of the upper layer in reasonable time. Since the upper layer is "a phase of variable composition" it is impossible to deduce its composition by extrapolation of the tie lines in the usual manner. If the homogeneous mixture obtained on heating is placed in the thermostat and allowed to stand without shaking for a week or two, separation of the layers is much more complete. Analyses of the lower layers lie on the same curve as those of mixtures that have been shaken,

indicating that equilibrium has been established. Analyses of the upper layer of these unshaken mixtures (indicated in Table I. by the letters "ns.") give a fair idea of the composition of the liquid crystalline phase, though most of the samples contained a little of the lower layer.

Lauric acid was purified by two fractional distillations of its methyl ester. Solutions and moist solids were analysed by (a) estimating excess alkali (or acid) by titration with standard acid (or alkali), acidic moist solids being titrated in 10 per cent. alcoholic solution, and (b) estimating the total lauric acid by precipitation with hydrochloric acid, the acid being collected, washed, and then titrated with standard alkali in 20 per cent. alcoholic solution. Phenolphthalein was used as indicator.<sup>2</sup>

Lauric anhydride ( $L_2O$ ), sodium oxide ( $Na_2O$ ), and water were chosen as the components of the system, since any other choice would involve negative concentrations. Analyses of the solutions and of the moist solids in equilibrium with them, expressed in terms of these components, are given in Table I. All analyses quoted are the mean of two concordant deter-

minations. In order to illustrate the most important points, these results are illustrated in the figure, in which triangular co-ordinates are used, and concentrations are expressed as mol. fractions except that an arbitrary value of 1000 has been taken for the molecular weight of water, following the device of McBain.

<sup>2</sup> McBain and Hay, *J. Chem. Soc.*, 1929, 589.

### Discussion.

The solid phases in equilibrium with solutions on the alkaline side are (1) sodium hydroxide monohydrate, (2) anhydrous sodium laurate, and (3) curd. Anhydrous sodium laurate is the stable phase in contact with concentrated solutions of alkali containing practically no soap, represented on the diagram by the line BA, the point A representing a saturated solution of sodium hydroxide. Curd is stable in contact with less strongly alkaline, neutral, and even slightly acid solutions represented in the diagram by the line BCDE. The change of phase at the point B was detected by a change in the direction of the tie lines, but more clearly by the change in appearance of the solid phase. (This change of direction of the tie lines is not apparent in the figure owing to the method of plotting adopted; the points representing anhydrous sodium laurate and sodium laurate monohydrate are too close for separate representation.) The anhydrous salt usually appeared under the microscope to consist of broken fragments that showed no external sign of crystalline form, though a few observations suggested that it crystallised in thin plates. The curd appears as a mass of matted fibres. A series of experiments, not recorded in Table I., fixed the triple point B between the limits 11.3-12.8 per cent.  $\text{Na}_2\text{O}$ . Curd is a form of sodium laurate, but owing to the relative positions in the diagram of the line BCDE and the points representing sodium laurate and its possible hydrates, our analyses do not throw much light on its degree of hydration. Tie lines from points on the curve near B indicate that it does not contain more than one molecule water of crystallisation, while tie lines from the section CDE are quite indecisive. Experiments of McBain and his collaborators indicate a higher degree of hydration for soap curds, but it is possible that the degree of hydration depends on their treatment and on the solution with which they are in contact.<sup>3</sup>

The profound influence of a slight excess of acid or alkali on the solubility of sodium laurate in the neutral region CDE is shown by the figures given in Table II., which have been obtained by recalculation of figures given in Table I. The compositions of nearly neutral solutions saturated with respect to curd are expressed in grams soap (LONa), and excess acid (LOH) or alkali (NaOH) per 100 grams solution.

As is well known, sodium chloride and other salts lower the solubility of soaps in the same way; this being probably the first known example of the phenomenon of "salting out." The raising of the solubility by excess acid is, however, unexpected; since lauric acid is a weak acid its effect should be negligible except for a small secondary effect in repressing hydrolysis and thus removing from solution the small amount of free alkali that is normally present. The phenomenon appears to be analogous to the Krafft effect.<sup>4</sup> In each case there is a sudden rapid increase in solubility; in the Krafft effect this is caused by a small increase in temperature, here by a small change in

<sup>3</sup> McBain and Salmon, *J. Chem. Soc.*, 1921, 119, 1374; McBain, Lazarus and Pitter, *Z. physik. Chem.*, 1930, 147A, 87.

<sup>4</sup> Krafft and Wiglow, *Ber.*, 1895, 28, 2566.

the other components of the solution. Before drawing any conclusions, however, it is desirable to investigate the system at other temperatures, and to ascertain whether the two phenomena have a common basis.

The effect of the repression of the solubility by alkali is to limit the area which represents the solution phase in the diagram to two narrow strips; one GA lying along the side of the triangle and representing solutions containing sodium hydroxide (0.40.6 per cent.), but practically no soap, the other GE lying along the neutral line and representing solutions containing soap (0.11.5 per cent.) with little excess acid or alkali.

As might be expected, lauric acid is practically insoluble in water and in dilute solutions of soap, but it dissolves appreciably in more concentrated solutions, as is shown in Table III. This seems only an example of a general phenomenon: Smith<sup>5</sup> has pointed out that concentrated solutions of soap dissolve appreciable quantities of organic compounds of the most varied types, and makes the reasonable suggestion that the soap micelle is capable of incorporating these organic substances.

The phases in equilibrium with the solution on the acid side are (1) lauric acid, (2) acid sodium laurate, and (3) a liquid crystalline phase. Lauric acid is in equilibrium with very dilute soap solutions (0 to about 0.1 per cent.); the co-existence of these phases is not indicated on the diagram. Acid soap is in equilibrium with a somewhat restricted range of more concentrated, but still dilute soap solutions (0.1-0.86 per cent.), represented in the diagram by the line FG. Analyses of moist solids indicate that its composition approximates to LONa, LOH, but that the ratio LONa:LOH increases as the concentration of soap in the solution in contact with it increases. It is impossible to draw any conclusions as to the degree of hydration from our analyses. Acid soap appears under the microscope to consist of very thin plates. It remains suspended in the mother liquor as a fairly stable colloidal suspension that exhibits well-marked striations on stirring, due to the plate-like form of the particles. The fact that acid soap forms these colloidal solutions suggests that it adsorbs sodium laurate from solution, and the variability of its composition is therefore not remarkable.

The liquid crystalline phase is in equilibrium with a wide range of slightly acid isotropic solutions (0.86-11.5 per cent. soap), represented in the diagram by the line EF. The compositions of the liquid crystals in equilibrium with these isotropic solutions are represented by the line HL. The equilibrium between these two phases can be followed into the region in which they are metastable with respect to formation of curd, as shown by the dotted lines EJ and HK. In general, compositions of liquid crystals approach those of isotropic solutions very closely, though the compositions of a particular liquid crystal and of the isotropic solution in equilibrium with it differ considerably. Study of these liquid crystals under the polarising microscope is much handicapped by the fact that they rapidly crystallise to acid soap at room temperature. Between crossed Nicols, the emulsion of liquid crystal in isotropic solution appears as a cloud of white circular discs—each covered by a similarly oriented black cross.

<sup>5</sup> Smith, *J. Physic. Chem.*, 1932, **36**, 1401, 1672 and 2455.

The concentration of the ordinary solution at the triple point isotropic solution—liquid crystal—curd, represented by the point E, was not determined directly, since the treatment required to get a solution in equilibrium with curd and suitable for analysis is so different from that required for the liquid crystal. Solutions in equilibrium with liquid crystal, after being analysed, were inoculated with curd. This grew in a solution containing 1.65 per cent.  $\text{Na}_2\text{O}$  and 12.68 per cent.  $\text{L}_2\text{O}$  and in more concentrated solutions, but not in less concentrated solutions.

## A DIRECT DEMONSTRATION OF BOUND WATER IN GELATIN GEL.

BY EMIL HATSCHKE.

*Received 24th March, 1936.*

When gelatin gels containing cobaltous chloride are allowed to dry at temperatures from  $15^\circ$  to  $30^\circ$  they turn a pure blue before all the water which they can lose at the latter temperature has evaporated. The water still remaining in the gel must therefore be considered as water bound by the gelatin in the sense that it is no longer free to hydrate the cobaltous chloride.

The quantitative determination of the amount thus bound seems of interest and offers no difficulty in principle. In practice it was found necessary to develop a technique by which gelatin films could be dried so as to have a uniform thickness, and therefore tint, and to remain flat until they had turned a pure blue. If free discs of gelatin gel a few mm. thick are allowed to dry in the usual way on gauze, the well-known complications arise: the rim dries more rapidly than the centre and thickens, and the discs bend into an anti-elastic surface, the colour of which is difficult to judge.

These complications are avoided, and flat discs are obtained, by casting the gel in circular frames, to which it adheres, in the following manner (Fig. 1): a polished metal plate A, the upper surface of which has been very lightly greased, is placed on a levelled table. A circular mould B, of hard wood, the lower face of which has been thinly coated with vaseline, is laid on the metal plate and weighted at the four corners. The periphery *bb* of the mould is varnished with shellac varnish; this does not destroy the adhesion of the gelatin but prevents its dehydration by the wood.

FIG. 1.

The mould is then filled with the gelatin sol C which is allowed to set for several hours or preferably overnight. When it has reached its full modulus or tensile strength the mould can be lifted off the metal plate by slowly tilting it; the disc of gel adheres to it and continues to do so during the drying process. The mould is hung up vertically, occasionally turned through  $180^\circ$  in its own plane, and the disc of gel allowed to dry until its colour is a pure blue. The change from an increasingly deep purple to pure blue is very sharp; if there is reason to suspect that the gel has been allowed to dry further than necessary, the discs can be placed in a moist atmosphere and allowed to take up water again until a purple tinge just begins to show.

To test how well defined the water content at the blue stage actually is, the following experiment was carried out. A specially thick disc was allowed to dry until the colour in transmitted daylight was judged to be a pure blue. It was removed from the mould in the manner to be described in the next paragraph and weighed; its weight was 3.342 gm. It was then placed in a moist atmosphere, carefully examined from time to time, and weighed when it showed an unmistakable purplish tinge. Its weight was then 3.365 gm., so that it had taken up 0.023 gm. of water. It was then dried to constant weight at  $100^\circ$  and left 2.510 gm. of dry residue, having lost 0.832 gm. of water compared with the original blue gel. The quantity of water—0.023 gm.—required to produce a marked change from pure blue according amounts to only 2.7 per cent. of the water content of the blue gel.

The discs dry to a fin round the periphery of the mould (see detail D) and are removed by cutting round the circle at *cc*. To determine the water content at the blue stage the discs are immediately placed in weighing bottles, weighed and then dried to constant weight at  $100^\circ$ , the temperature being raised very gradually so as to avoid melting.

If  $p_1$  is the weight of the blue gel and  $p_2$  that of the residue at  $100^\circ$ ,  $p_1 - p_2 = w$  is the weight of water in the blue gel. The dry residue consists of gelatin dried at  $100^\circ$  and anhydrous  $\text{CoCl}_2$  in the ratio  $g:c$ , which can be calculated from the known quantities of gelatin and  $\text{CoCl}_2$ ,  $6\text{H}_2\text{O}$  used in preparing the sol. The weight  $p_2$  of gelatin in the dry residue is accordingly

$$p_2 = p_2 g / (g + c)$$

and the percentage of water in the blue gel  $H$

$$H = 100w / (w + p_2).$$

Some authors define the gel by stating the weight  $h$  of water per gm. of dry gelatin which is

$$h = w / p_2.$$

Gelatin sols, the particulars of which are given below, were prepared from four different brands; the iso-electric gelatin was kindly supplied by Dr. Dorothy Jordan Lloyd. The sols usually contained 10 gm. of water per gm. of gelatin; although this low concentration prolongs the period of drying it permits the use of lower temperatures and makes it easier to obtain gels free from air bubbles. The relevant figures are as follows:—

(A) 10 gm. air-dry Nelson's "Transparent" gelatin + 5 gm.  $\text{CoCl}_2$ ,  $6\text{H}_2\text{O}$ . A sample of the gelatin dried at  $100^\circ$  gave 86.8 per cent. of dry matter. The ratio  $g/c$  is therefore (as 1 gm.  $\text{CoCl}_2$ ,  $6\text{H}_2\text{O}$  gives 0.546 gm.  $\text{CoCl}_2$ ):—

$$g/c = 8.68/2.730.$$

(B) 10 gm. gelatin from S. Combier, Annonay, dried at  $100^\circ$ , + 5 gm.  $\text{CoCl}_2$ ,  $6\text{H}_2\text{O}$ :—

$$g/c = 2.00/0.546.$$

(C) 10 gm. air-dry iso-electric gelatin + 5 gm.  $\text{CoCl}_2 \cdot 6\text{H}_2\text{O}$ . A sample dried at  $100^\circ$  gave 86.7 per cent. of dry matter:—

$$g/c = 8.67/2.730.$$

(D) 10 gm. Coignet "gold label" gelatin, dried at  $100^\circ$  + 5 gm.  $\text{CoCl}_2 \cdot 6\text{H}_2\text{O}$ :—

$$g/c = 2.00/0.546.$$

The results are as follows:

- (A)  $p_1 = 2.143$  gm.;  $p_2 = 1.538$  gm.;  $w = 0.605$  gm.;  $p_3 = 1.170$  gm.  
 $H = 34.0$  per cent.;  $h = 0.51$ .
- (B)  $p_1 = 2.590$  gm.;  $p_2 = 1.850$  gm.;  $w = 0.740$  gm.;  $p_3 = 1.453$  gm.  
 $H = 33.7$  per cent.;  $h = 0.51$
- (C)  $p_1 = 2.005$  gm.;  $p_2 = 1.490$  gm.;  $w = 0.515$  gm.;  $p_3 = 1.132$  gm.  
 $H = 31.4$  per cent.;  $h = 0.43$
- (D)  $p_1 = 1.840$  gm.;  $p_2 = 1.375$  gm.;  $w = 0.465$  gm.;  $p_3 = 1.060$  gm.  
 $H = 30.4$  per cent.;  $h = 0.44$ .

### Discussion of Results.

Gelatin gels of different origin have been shown to contain between 30.4 and 34.0 per cent. of water which is not free to hydrate cobaltous chloride. These figures are in good agreement with the values for bound water found by entirely different methods. Thus T. Moran<sup>1</sup> finds: "... when the water content falls to 35.34 per cent. there is no separation of ice at any temperature. . . . This undoubtedly suggests that water is present in the gel in two states, which may be distinguished as 'bound' and 'interstitial' water. Bound water is merely water which is incapable of being frozen."

In the present investigation "bound" water is water which is incapable of hydrating cobaltous chloride and the agreement between the percentages of such water and Moran's values, while undoubtedly striking, must not be over-emphasised. Apart from other points Moran used an ash-free and iso-electric gelatin, whereas the gels described here contained cobaltous chloride, *i.e.* electrolyte in considerable amounts. It is almost certain that this affects the percentage of bound water, and there seems to be a possibility of obtaining a new insight into the effects of the Hofmeister series by investigating gels containing either cobaltous salts with different anions, or mixtures of cobaltous chloride with neutral salts of different anions. Work in these directions is in progress.

### Summary.

Gelatin gels containing cobaltous chloride have been shown to contain from 30 to 34 per cent. of bound water incapable of hydrating the cobalt salt, a value in good agreement with the figures for bound water found by other methods.

# THE MAGNETIC SUSCEPTIBILITY OF CHLORINE HEXOXIDE.

BY J. FARQUHARSON, C. F. GOODEVE AND F. D. RICHARDSON.

*Received 23rd March, 1936.*

A red oily liquid was detected by Bowen<sup>1</sup> in a study of the photochemistry of chlorine dioxide. The substance was isolated by Bodenstein, Hardeck and Padelt,<sup>2</sup> and was found by them to contain three atoms of oxygen to one of chlorine. Its molecular weight, when dissolved in carbon tetrachloride, was found to be 153.6, and it was called "chlorine hexoxide" (M.W. 167). Goodeve and Todd<sup>3</sup> showed that in the gaseous state it existed entirely as  $\text{ClO}_3$ , and this form was called "chlorine trioxide." It was with the object of determining the composition of the liquid and solid phases that the following investigation of the magnetic susceptibility was carried out.

It is a general rule that paramagnetism in molecules is associated with an unbalanced electronic structure. Any molecule with an odd number of circumnuclear electrons must be unbalanced, and therefore paramagnetic. This has been shown to be true for NO (15 circumnuclear electrons),  $\text{NO}_2$  (23), and  $\text{ClO}_2$  (33). It can be assumed that  $\text{ClO}_3$  (41) will also be paramagnetic.

If a molecule with an odd number of electrons polymerises into a double molecule, the resulting polymer may be diamagnetic. For example, in the equilibrium

$\text{NO}_2$  is strongly paramagnetic, and  $\text{N}_2\text{O}_4$  diamagnetic. It should be noted that molecules with an even number of electrons are not necessarily diamagnetic. The oxygen molecule, for example, is strongly paramagnetic by virtue of its being in a  $^3\Sigma$  state. As a general rule, however, molecules with an even number of electrons are in a  $^1\Sigma$  state, and are diamagnetic.

The fact that paramagnetic  $\text{NO}_2$  polymerises to diamagnetic  $\text{N}_2\text{O}_4$  has been used by Havens<sup>4</sup> in order to arrive at the temperature variation of the susceptibility of  $\text{NO}_2$ . He studied the magnetic susceptibilities of equilibrium mixtures of the two gases at different temperatures. The amount of  $\text{N}_2\text{O}_4$  was determined from other data, and, allowing for its diamagnetism, the susceptibility of  $\text{NO}_2$  was calculated. He found it to conform to Van Vleck's equation (see below). This equation has also been found to hold for chlorine dioxide.<sup>5</sup>

If chlorine trioxide polymerises to  $^1\Sigma \text{Cl}_2\text{O}_6$  in the condensed state, the substance will be diamagnetic. If there is an equilibrium between the two molecular species there may be paramagnetism to a greater or

<sup>1</sup> E. J. Bowen, *J.C.S.*, 1923, 123, 2328; H. Booth and E. J. Bowen, *J.C.S.*, 1925, 127, 510.

<sup>2</sup> M. Bodenstein, P. Hardeck and E. Padelt, *Z. anorg. Chem.*, 1925, 147, 233.

<sup>3</sup> C. F. Goodeve and F. A. Todd, *Nature*, 1933, 132, 514.

lesser extent, depending on the number of  $\text{ClO}_3$  molecules present, or there may be a small diamagnetic effect. From these considerations, it is obvious that it is possible to find the proportions of  $\text{ClO}_3$  and  $\text{Cl}_2\text{O}_6$  in the mixture if its susceptibility and those of the pure components are known.

## Experimental.

### Susceptibility Measurements.

The  $\text{ClO}_3 - \text{Cl}_2\text{O}_6$  mixtures used in this research were prepared by mixing, at  $0^\circ \text{C}$ ., a stream of oxygen containing 75 per cent. by weight of chlorine dioxide, with a stream of ozonised oxygen containing about 10 per cent. ozone. The flow speeds were roughly in the ratio 1 : 8. Solid crystals of the hexoxide were deposited on the walls of the reaction chamber and after fractional distillation their melting-point was about  $+ 3.5^\circ \text{C}$ .

The mixture was finally distilled into the trap shown in Fig. 1 a, which was cooled to  $-30^\circ \text{C}$ . The hexoxide on warming and melting, ran down into the cylinder V. A vacuum was maintained to remove any traces of impurity formed by decomposition during this last operation. The cylinder, immersed in liquid air up to the level of the hexoxide, was then sealed off at the constriction and a glass hook sealed on the top. The specimen could then be stored indefinitely in a solid carbon dioxide-alcohol mixture.

A Guoy method was used for the magnetic measurements. The specimen was suspended from the arm B of a weighing balance (Fig. 1 b), so that one end of the cylinder was in a uniform field of about 5500 Gauss and the other end in a position where the field was negligible.

The apparatus for cooling the specimen consisted of a copper tube up which passed dry nitrogen, in a Dewar vessel containing liquid air to cool the gas. This vessel was of a special design with a constriction at its centre in order that the gap between the pole pieces, P, P of the magnet should be as small as possible. The copper tube C was thermally insulated from the outside air by means of a glass tube G. This was continued into another copper tube D to allow the rising gas to be heated rapidly to room temperature to prevent condensation of water vapour on the suspension. Temperatures were measured by means of the copper constantan thermocouple T, which was insulated from the copper tube by means of a glass tube and asbestos. This thermocouple was initially calibrated with a standard Pt—Pt.Ir couple suspended in the position to be occupied by the sample of the hexoxide mixture.

The force acting on the substance in a magnetic field is measured by "g" times the difference in weight  $\Delta W$  with and without the field, and is given by the equation:—

$$F = \Delta W \cdot g = \frac{1}{2}(K_1 - K_2)AH^2,$$

FIG. 1.—The apparatus.

where  $K_1$  is the volume susceptibility of the specimen;  $K_2$  that of the medium in which it is suspended (in this case nitrogen);  $H$  the magnetic field, and  $A$  the cross-section of the specimen.  $K_2$  can be assumed as negligible in comparison with  $K_1$ .

Values for  $\Delta W$  were determined first for the cylindrical tube plus the hexoxide, for a series of temperatures. The values for the empty tube were then determined over the same temperature range. The whole apparatus was standardised by repeating with the tube filled with conductivity water to the level of the original hexoxide. From the value for water,\*  $0.72 \times 10^{-6}$ , the volume susceptibility of the hexoxide can be calculated, using the relative values of  $\Delta W$ . The mass susceptibility is obtained from this and the density at the freezing point.

**Results.**—The measurements were carried out over a temperature range  $-40^\circ \text{C.}$  to  $+10^\circ \text{C.}$  This range was obtained by allowing the liquid air in the Dewar vessel to distil slowly away. Measurements above  $+10^\circ \text{C.}$  could not be made, as the hexoxide decomposes, producing chlorine dioxide above this temperature. The results are shown in Fig. 2. Curve A is drawn through the values of  $\Delta W$  for the tube filled with the

FIG. 2.—The results.

hexoxide mixture. Measurements were made on two successive days, those on the second being indicated by circles. The values of  $\Delta W$  are negative (diamagnetic). The values for the empty tube are shown by curve T. In this case  $\Delta W$  is positive. The values for the hexoxide mixture alone are shown by curve Ac, which is the sum of curves A and T. It is seen from the figure that the hexoxide mixture is diamagnetic throughout the temperature range and

that the susceptibility decreases with increasing temperature. The diamagnetism shows that  $\text{Cl}_2\text{O}_6$  is in a  $^1\Sigma$  state.

One series of measurements was made after leaving the specimen for fifteen minutes at  $20^\circ \text{C.}$  The results are shown by curves B and Bc. Owing to the strong paramagnetic effect of the dioxide (and oxygen) now present in the mixture—an effect which should decrease with rise in temperature—this curve lies well below that for the pure specimen, the amount of separation being approximately proportional to the absolute temperature.

### Density Measurements.

From the weighings made for the above determinations the density was calculated fairly accurately and found to be 2.00 gms. per c.c. A more accurate determination was made by distilling about 1 c.c. of the hexoxide, used for the magnetic measurements, into a small graduated

\* Landolt Börnstein, *Physikalisch-Chemische Tabellen*, 1923, p. 1203.

tube with a capillary neck. In this apparatus the coefficient of expansion was also found. The results were as follows:—

Density of the liquid hexoxide at  $+3.5^{\circ}\text{C.}$  .  $2.023 \pm .003$  gms. per c.c.  
 Specific volume . . . . .  $0.494$  c.c. per gram.  
 Coefficient of cubical expansion . . . . .  $12 \pm 3 \times 10^{-6}$  c.c. per c.c. per degree C.

### Theoretical Susceptibilities of $\text{ClO}_3$ and $\text{Cl}_2\text{O}_6$ .

The molar susceptibility ( $\chi_{\text{mol.}}$ ) of  $\text{ClO}_3$  can be calculated from the simplified relation of Van Vleck<sup>7</sup>:—

$$\chi_{\text{mol.}} = \frac{4N\beta^2S(S+1)}{3KT},$$

where  $N$  is the number of molecules per gram molecule;  $\beta$  the Bohr magneton,  $0.9174 \times 10^{-20}$  e.m.u.;  $S$  the spin quantum number, and  $K$  the Boltzmann constant. It is assumed that all the electrons, except the odd one, are paired, and therefore  $S = \frac{1}{2}$ . The mass susceptibility is then found by dividing  $\chi_{\text{mol.}}$  by the molecular weight. The values so calculated for a number of temperatures are shown in column 2 of the Table.

Temperature.	Mass Susceptibilities $\times 10^6$ (Ergs gram <sup>-1</sup> gauss <sup>-2</sup> ).			Per Cent. $\text{ClO}_3$ by Weight.	$K \times 10^3$ .
	$\text{ClO}_3$ .	$\text{Cl}_2\text{O}_6$ .	Experimental.		
-40	19.15	-0.405	-0.264	0.721	2.54
-30	18.36	"	-0.250	0.775	2.94
-20	17.64	"	-0.255	0.826	3.34
-10	16.98	"	-0.251	0.886	3.85
0	16.36	"	-0.247	0.943	4.36
+10	15.79	"	-0.243	1.001	4.91

The value for the molar susceptibility of  $\text{Cl}_2\text{O}_6$  can be calculated by adding Pascal's experimental atomic values.<sup>8</sup> For Cl his figure is  $-20 \times 10^{-6}$  e.m.u., and for oxygen  $-4.6 \times 10^{-6}$ , thus giving a value for the molar susceptibility of  $-67.6 \times 10^{-6}$ , and for the mass susceptibility of  $-0.405 \times 10^{-6}$ . This figure is supported by that obtained from Pauling's theoretical ionic values.<sup>9</sup> Here it is necessary to assume some such structure as  $\text{Cl}^{7+} + \text{Cl}^{5+} + 6\text{O}^{2-}$  for  $\text{Cl}_2\text{O}_6$ , which gives  $\chi_{\text{mol.}} = -(1.2 + 5.7 + 6 \times 12.6) \times 10^{-6} = -82.5 \times 10^{-6}$ . This is subject to a reduction of about 20 per cent., owing to the formation of linkages. The susceptibility thus becomes  $\chi_{\text{mol.}} = -66.5 \times 10^{-6}$ , which adds confirmation to the value taken for this work,  $\chi = -0.405 \times 10^{-6}$ . As diamagnetism is independent of temperature, it is unnecessary to make any correction for temperature variation.

### Discussion.

The value of the mass susceptibility of the chlorine hexoxide calculated from the values of  $\Delta W$  in Fig. 2 are shown in column 4 of the Table. It is seen that the diamagnetism of the mixture is less than the theoretical value for  $\text{Cl}_2\text{O}_6$ . This is probably due to the presence of a paramagnetic substance in equilibrium with  $\text{Cl}_2\text{O}_6$ , and increasing in amount with rise in temperature. As the substance exists almost entirely as  $\text{ClO}_2$  in the gaseous phase, it is most likely that there is some dissociation in the liquid and solid phases as well. The percentage by weight of the trioxide, calculated by assuming the difference between the experimental and theoretical values to be due exclusively to its presence, is given in column 5. Chlorine dioxide, if present, would act exactly as the trioxide as regards its effect on the susceptibility, and the values in this column would have to be reduced by a fixed amount. From the melting-point and the colour of the specimen at low temperatures, properties which are markedly affected by small amounts of chlorine dioxide, it is considered that the effect of traces of this oxide is not greater than the following limits of error :—

These observations are subject to a number of possible errors. The weighings were carried out to 1/20th mgm. Assuming that the theoretical values of the mass susceptibilities are correct, the errors in weighing lead to an uncertainty in the values in column 5 of  $\pm 0.5$ . The theoretical values for  $\text{ClO}_2$  are probably sufficiently accurate not to affect these limits of error. The additivity principle used to determine the value of  $-0.405 \times 10^{-6}$  for  $\text{Cl}_2\text{O}_6$  has been fairly well established,<sup>9</sup> but its application is subject to confirmation by a study of other diamagnetic oxides of chlorine. Any error here would lead to a disproportionate error in the final results. The error in absolute temperature is rather indefinite, due both to the time lag in the warming of the specimen and the temperature gradient up the cylinder. The total time of the experiment was two and a half hours and near the melting-point this error was not more than a few degrees.

The values of the equilibrium constant  $K_c$  are given in the last column. The concentrations are expressed in gram molecules per litre. The logarithm of this constant, when plotted against the reciprocal of the absolute temperature, gives a straight line and the results may be expressed by the following equation :—

$$\log_{10} K_c = C - \Delta U / 2.3 RT = -0.974 - 1730 / 2.3 RT.$$

The heat of dissociation of  $\text{Cl}_2\text{O}_6$  is therefore  $1730 \pm 500$  calories per gram molecule. No break in the curve was observed at the melting-point.

The low dissociation in the condensed state and the almost complete dissociation in the gaseous state<sup>3</sup> are not incompatible. Should an equilibrium constant of the same order as that above apply to the gaseous state, the equilibrium would be almost entirely on the side of the  $\text{ClO}_2$ , owing to the very low vapour pressure.

The above work was carried out with the financial assistance of the Department of Scientific and Industrial Research and of Imperial Chemical Industries, Ltd.

### Summary.

The susceptibility of chlorine hexoxide has been measured over a temperature range  $-40^{\circ}$  to  $+10^{\circ}$  C. The density and coefficient of cubical expansion have also been determined.

On the basis of theoretical values for the susceptibilities of  $\text{Cl}_2\text{O}_6$  and  $\text{ClO}_2$ , the percentage of  $\text{ClO}_2$  present in the mixture at various temperatures has been calculated, together with the corresponding equilibrium constants.

An approximate value for the heat of dissociation has been determined from these constants.

## TRANSPORT NUMBERS OF PARAFFIN-CHAIN\* SALTS IN AQUEOUS SOLUTION.

PART I.—MEASUREMENT OF TRANSPORT NUMBERS OF  
CETYLPIRIDINIUM AND CETYLTRIMETHYLAMMONIUM  
BROMIDES AND THEIR INTERPRETATION IN TERMS  
OF MICELLE FORMATION. WITH SOME DATA ALSO FOR  
CETANE SULPHONIC ACID.

BY G. S. HARTLEY, B. COLLIE,<sup>†</sup> AND C. S. SAMIS.<sup>‡</sup>

*Received 13th January, 1936.*

The difficulty of drawing correct conclusions about micelle formation from conductivity data alone has been discussed in some detail elsewhere.<sup>1</sup> By micelle formation we mean the aggregation of large organic ions of like sign which occurs in aqueous solutions of several types of organic salts of high equivalent weight. Although aggregation of ions of like sign only will, according to the well-known reasoning of McBain,<sup>2</sup> increase their mobility, micelle formation may not produce an increase of equivalent conductivity. If the micelles are large, the aggregation will considerably increase the effect of coulomb attraction between the constituent ions and ions of opposite sign (which we shall call "gegenions"). The consequent adherence of gegenions to the micelle will tend to reduce both the mobility of the micelle and the equivalent conductivity. The effect on the latter will be relatively greater than on the former. The direct braking effect of the Debye-Hückel "atmospheres" will also reduce both these quantities, and probably the former relatively more than the latter, but, although in micelle-containing solutions their effect will be great, it will probably be less important than that of the gegenions actually adhering to the micelle.<sup>3</sup> If, therefore, micelle

\* A more exact name which will be used in subsequent publications in place of the "long-chain" salts used in earlier ones.

<sup>†</sup> Experimental work entirely done by the latter authors.

<sup>2</sup> Hartley, *ibid.*, 1935, **31**, 31.

formation causes a decrease rather than an increase of equivalent conductivity, we may still find an increased mobility for the organic radical, and shall almost certainly find an increase of its transport number.

This is well illustrated by the equivalent conductivity-concentration curves for the two dyes, methylene blue and "meta" benzopurpurine, and for the paraffin-chain salt, cetylpyridinium chloride.<sup>1</sup> The first has an equivalent conductivity rising *above its infinite dilution value* in very dilute solution, a phenomenon which seems to admit no other interpretation than the formation of (probably small) micelles. The second, which transport number measurements have conclusively shown to contain micelles, has an *apparently* normal conductivity. The third shows, at a concentration of about  $N/1000$ , a very sudden *fall* of equivalent conductivity which, there is nevertheless very strong evidence<sup>4, 5</sup> to show, is accompanied by the formation of large micelles.

In the present work, transport number measurements on two paraffin-chain salts are described. The objects in carrying out this work were three: (a) to obtain yet more evidence than was before available that the sudden fall of conductivity is due to the formation of micelles and consequent association of the gegenions with them; (b) to measure the mobility of the micelles and, if possible, to obtain some idea of the fraction of the gegenions adhering to them and, hence, of the number of paraffin-chain ions contained in each; (c) to find a satisfactory explanation of the *rise of equivalent conductivity* with increasing concentration which is found in most paraffin-chain salts in moderately concentrated solutions, since our knowledge that micelle formation produces the steep *fall of equivalent conductivity* found in the dilute solutions necessitates a reconsideration of McBain's almost classical theory of the former phenomenon.

### Experimental.

The method and apparatus used for the transport number determinations have been fully described elsewhere.<sup>6</sup> A brief outline only will be given here. When practicable, the moving boundary method is greatly to be preferred to the Hittorf method, since it enables continuous measurements to be made instead of depending on four analyses only (and frequently two are not practicable, owing to the non-existence of sufficiently accurate analytical methods). In each experiment with the moving boundary method we have an internal check on the accuracy of the results, and moreover the whole experiment can be carried out in a shorter time than with the Hittorf method. If we wish to determine the transport numbers of large radicals directly by the moving boundary method, however, we shall frequently be faced with difficulty in finding salts to act as indicators, because these must have a radical of like polarity which has a *lower* mobility than the one we are concerned with. For the largest and slowest organic radicals it becomes necessary, therefore, for the radical which is to be investigated to *follow* one which is *faster*. Measurement of the current and volume velocity of the boundary gives us the transport number of the *leading* radical, because the concentration of this remains constant at its initial value in the solution into which the boundary is advancing. It does not, however, give us the transport number of the *following* radical, because the concentration of the latter, in the solution which the boundary leaves behind, is determined, not by its initial concentration (except insofar as convection may cause disturbance), but by the concentration of

<sup>1</sup> Malsch and Hartley, *Z. physik. Chem.*, 1934, 170A, 321.

<sup>3</sup> Hartley, Drew and Collie, *ibid.*, 1934, 30, 648.

the leading radical and the several transport numbers, the relationship being given by the equation :—

$$\frac{T_R}{C_R} = \frac{T_X^K}{C_X^K} \quad . \quad . \quad . \quad . \quad . \quad . \quad (1)$$

where  $T$ 's are transport numbers,  $C$ 's concentrations, suffixes  $R$  and  $X$  denote leading and "indicator" radicals, and the superscript  $K$  refers to the "synthetic" solution behind the boundary. This we call the Kohlrausch solution after the discoverer of equation (1). The balanced boundary apparatus is designed to displace the Kohlrausch solution, slowly and continuously as it is formed, into a side tube where its conductivity is measured. We thus *measure the concentration* of the Kohlrausch solution and, using a leading radical whose transport number in the leading solution is known from independent measurements, we then derive the desired transport number from the Kohlrausch equation.

The use of the apparatus had in some respects to be modified to adapt it to measurement of paraffin-chain salts at 35° C. These modifications are described with reference to Fig. 4 of the previous paper,\* to which paper the reader is referred for a full description of the original technique. The use of grease on the stopper of the electrode vessel B was entirely avoided, as it would have been emulsified. The ungreased stopper, however, permitted solution to leak out when the level of the liquid which should be expressed from G rose above the level of the stopper. Accordingly, a wide tube was fitted over G, open at the bottom and closed by a rubber tube and pinchcock at the top, and thermostat water was sucked up into it, thereby lowering the pressure at the top of G below atmospheric. This also avoided crystallisation of the salt in G, which occurred when this was left unprotected at room temperature. As it was thought that electrical leakage might occur, due to the trickling of solution over the edge of G into the thermostat water, which would be immediately below it (a possibility made more serious by the wetting power of the paraffin-chain salt solution), a second tube was fitted, outside G but inside the first, open at the top and attached to G at the bottom (which was narrowed) by a sleeve of rubber tubing. The top of this tube stood above that of G, and so the thermostat water could be still further raised inside the outer tube. Greater care was necessary in the manipulation of the bubble in the Y, owing to the low surface tension of the upper solution. Because bubbles formed in these solutions have a great reluctance to unite and may adhere very tenaciously to the wire electrodes, it was also necessary to wash out any froth formed in the upper tubes of the Y by allowing solution to sweep out at G and then drawing the meniscus back very carefully to the Y. Apart from this, the experiments seemed to be in no way complicated by replacement of LiCl by the colloidal electrolyte, but the first results obtained were rather erratic. It was considered that this might be due to dilution of the Kohlrausch solution by original "indicator" solution in the right hand limb of the Y. Accordingly, solution was drawn up the right hand limb of the Y from time to time through the stop-cock and tube attached to F. Readings of the resistance were taken every half hour, and about one-third of the solution that had entered the electrode tube since the previous reading was then drawn back in this way. The constancy of the readings was considerably improved, but they were still subject to greater erratic variation than in the work with the alkali chlorides.

A new apparatus has recently been constructed making more suitable provision for the modifications of procedure described, in particular by introducing a second piston and cylinder connected to the vessel B. This piston is of only half the diameter of the other and is caused, by a common mechanism, to *ascend* at the same linear velocity with which the larger one *descends*, so that one quarter of the solution ascending in the boundary tube is *continuously* diverted up the right hand limb of the Y. Some of the

measurements here recorded have been obtained with the new apparatus, which gives very much more concordant results, and these agree very well with the mean results obtained in the old apparatus. This new apparatus will be described in detail in a later publication.

The salts cetylpyridinium bromide and cetyltrimethylammonium bromide were used in this investigation. Potassium, or, in some cases, barium bromide, was used as leading electrolyte. Platinum gauze immersed in ferric bromide solution provided a satisfactory non-gassing cathode which did not give rise to anions more mobile than bromide. Silver-plated platinum gauze served satisfactorily for the anode, solid silver bromide being quantitatively formed. Owing, presumably, to interference of the paraffin-chain salt with the crystal growth, the silver bromide did not adhere to the electrode, but formed instead a fine precipitate.

Both paraffin-chain compounds were obtained from cetyl bromide kindly supplied by Imperial Chemical Industries, Ltd., and subjected to careful fractionation by our colleague, Dr. N. K. Adam, to whom we are greatly indebted. Its bromine content was found to be  $26.25 \pm 0.5$ , agreeing well with the theoretical 26.2 ( $C_{18}$  has 28.8 and  $C_{18}$ , 24.9 per cent.). Cetylpyridinium bromide was prepared by heating the cetyl bromide with 20 mols. per cent. excess of pyridine, purified by the method of Arndt and Nachtwey,<sup>7</sup> with constant stirring at 120–30° C., for four hours. The product was several times recrystallised from water and then from redistilled acetone, and dried in a vacuum desiccator over phosphorus pentoxide. The bromine content, found gravimetrically by precipitation with  $AgNO_3$  in alcoholic solution, was 20.68 per cent. (theoretical 20.79 per cent.). The trimethylammonium salt was prepared by refluxing cetyl bromide with excess of 10 per cent. solution of trimethylamine in nitromethane (prepared by boiling off trimethylamine from 30 per cent. aqueous solution, through lime, into nitromethane), using an ice-cooled condenser to prevent loss of trimethylamine. The product was washed with acetone, recrystallised several times from water, and dried over phosphorus pentoxide. Bromine content 21.79 per cent. (theoretical 21.93 per cent.). Both preparations gave perfectly clear aqueous solutions above about 30° C. The water used had a specific conductivity  $0.2-0.4 \times 10^{-8}$  ohms<sup>-1</sup> cm.<sup>-1</sup> as collected in  $CO_2$ -free air from a special still, but no precautions were taken to prevent access of  $CO_2$  in the transport number apparatus.

All solutions were made up by volume \* at 35° C., at which temperature all the measurements here recorded were made. Densities were separately determined in order to convert the concentrations to the mass-of-solvent basis for calculation of the Hittor' transport numbers.<sup>8</sup> Knowledge of the densities was also necessary to confirm that the Kohlrausch solution in the transport apparatus was less dense than the leading solution below it, a condition which is, of course, necessary for stability of the (descending) boundary.

Conductivities were determined by means of a direct-reading alternating current bridge, employing three frequencies: about 1000,  $1000 \times \sqrt{2}$  and  $1000 \times 2$  cycles per sec. The apparent leak in the leads from cell to bridge (due to non-ideal capacity) and errors due to the oscillator-bridge coupling (arising because the connection of cell to the dial resistance box was directly

<sup>7</sup> Arndt and Nachtwey, *Ber.*, 1926, **59**, 448.

\* In the manipulation of these cationic paraffin-chain salt solutions in glass vessels, difficulty is frequently encountered owing to their leaving the glass in a peculiar condition, so that when water is introduced into a vessel that has contained a solution, the walls behave as though they were extremely greasy. Probably the cations are adsorbed "head-on" to the negatively charged glass, and thus leave exposed a monomolecular layer of paraffin "tails." The solutions themselves will wet this layer unless they are extremely dilute. Small air bubbles also adhere to glass or platinum very tenaciously when a very dilute solution is used. The layer may be removed by washing with alcohol or acetone.

earthed) were determined by calibration with a standard resistance box in the cell position. Error due to resistance-capacity shunts in the cell when high resistances were being measured was eliminated by extrapolation against square of frequency to zero frequency. The cells used in this work were of the type described by Robinson and Moillet,<sup>8</sup> except that, for the most dilute solutions, a large cell was used of a type that permitted dilution to be carried out in the cell without access of carbon dioxide. The electrodes were blackened except in the dilution cell, which was used only for very low concentrations. Equivalent conductivities are given in Table I.

The data for the transport number determinations are collected in Table II. From the known volume concentration of KBr or BaBr<sub>2</sub> (column 1), and the volume concentration (column 7) of paraffin-chain salt in the Kohlrausch solution, determined by conductivity the transport number of the organic radical (column 8) was calculated from the Kohlrausch equation (1), the concentrations being converted to the mass-of-solvent basis for use in this equation. In column 2 is given the mean of the numerical deviations of the resistance of the Kohlrausch solution from the mean resistance, expressed as a percentage of the latter, and in column 3 the time over which readings included in the average were taken (at half-hour intervals). In the column headed "drift" is given the average resistance for the first half of this time subtracted from that for the latter half, expressed as percentage of the complete average. The time that was allowed to elapse before readings were included in the average is given in column 5, and the initial concentration of the paraffin-chain salt solution in column 6. It will be noticed that results obtained with the new apparatus (denoted by \*), and those obtained using BaBr<sub>2</sub> in the leading position (†) are in good agreement with the other results. BaBr<sub>2</sub> was used to check the figures obtained with KBr because, owing to the great density difference of the leading and Kohlrausch solutions when the former is used, error due to convection, which is the most probable source of error in the more concentrated solutions, will be greatly reduced. The

good agreement is evidence that convection is not causing appreciable error.

The value of  $T_K$  in the KBr solutions was taken to be 0.483 at all the concentrations used, in accordance with the measurements of Longworth\* at 25° C., assuming the temperature effect on transport number to be negligible for this salt, as would be expected from the temperature coefficients of ionic conductivities given by Kohlrausch and Holborn.<sup>10</sup> For  $T_{Ba}$  in BaBr<sub>2</sub>, the values for BaCl<sub>2</sub> at 25° C., at the relevant concentrations, were taken from the work of Jones and Dole<sup>11</sup> and allowance made for the bromide-chloride difference and for the temperature change on the basis of the figures given by Kohlrausch and Holborn. This gave  $T_{Ba}$  in BaBr<sub>2</sub> at 35° C., 0.7 per cent. less than  $T_{Ba}$  in BaCl<sub>2</sub> at 25° C. The figures obtained in this way are probably more accurate than any direct measurements at present published. As the transport number of the paraffin radical in our results is simply proportional to the  $T_K$  or  $T_{Ba}$  value (the concentrations being unaffected) correction may be made at once when more accurate data are available.

Within a certain range, the transport number in the paraffin-chain salt solution is changing so rapidly with concentration that two different Kohlrausch solutions could be obtained with the use of the same leading solution.\* The lower one was obtained by starting with a still lower paraffin-chain salt concentration, and the higher by starting with a still higher concentration. The adverse density gradient that must have existed in experiments where the latter procedure was adopted did not give rise to convection trouble, presumably because the low concentrations and the lightness of these salts in water did not cause a density different sufficient to compete with the upward bulk flow of the solution. It was not thought necessary to attempt to obtain any points in the middle of this range, which is about from  $N/700$  to  $N/300$ .

## Discussion of Results.

### I. Qualitative.

The total equivalent conductivities and the transport numbers of the organic radicals in the two paraffin-chain salts are plotted against the square root of volume concentration in Fig. 2. The former quantity falls very steeply and rather suddenly at about  $N/1000$ , as in other unhydrolysed salts with 16 carbon atoms in the chain.<sup>12, 5</sup> The transport numbers rise very rapidly in the range where the total equivalent conductivities fall, and reach values much above unity in concentrations well below  $N/100$ . The greater-than-unity values mean, of course, that the bromide transport numbers are negative, *i.e.* that more bromine is being carried towards the cathode by more-than-univalent cations than is migrating in the free state to the anode. In a salt whose single cations are univalent, this admits of no other explanation than the formation of multiple cations—micelles.

Below  $0.0008N$  we have experimental points which, though they are not very accurate, are obviously not far removed from the value  $-0.22$

\* Reference to Fig. 1 which is a qualitative diagram in which the variation is exaggerated for the sake of clarity, will show that there must, in general, be three solutions to the Kohlrausch equation if there is more than one. For a

given leading solution the three Kohlrausch concentrations will be represented by the intersections with the transport number curve of a straight line whose slope is equal to  $T_R/C_R$ . In the central region it is clear that  $dT/dC$  is greater than  $T/C$  and, therefore, concentration disturbances will tend to be propagated more rapidly than the boundary itself, a possibility discussed by Hartley and Moilliet.<sup>13</sup> It can be shown that the intermediate Kohlrausch concentration is not experimentally attainable,

and that, if an initial concentration of paraffin-chain salt near to it were used, a Kohlrausch solution of either the one extreme or the other would be obtained, but only as a small region moving after the boundary and gradually increasing in depth.

FIG. 1.

<sup>13</sup> Hartley and Moilliet, *Proc. Roy. Soc.*, 1933, 140A, 141.

—predicted for infinite dilution from the conductivity data: below this concentration there is presumably no appreciable aggregation. The abruptness of the change is easily explicable by the mass-action law according to the reasoning of Bury,<sup>14, 8, 15</sup> if the micelles formed are large and if small aggregates are not present in considerable amounts.

With regard to both conductivity and transport numbers, the two salts studied are extremely similar, the chief differences being that the critical concentration for the pyridinium compound is slightly lower than that for the trimethyl-ammonium compound (0.00075 as against 0.0009*N*), and that the maximum transport number is slightly higher. For the sake of simplicity, therefore, we shall confine the further discussion to the latter salt, for which the data are rather more extensive.

FIG. 2.—Total equivalent conductivity and paraffin-chain transport number for cetylpyridinium (O) and cetyltrimethylammonium (□) bromides at 35° C. \* and † distinguish points obtained with new apparatus and  $\text{BaCl}_2$  respectively.

In Fig. 3 is plotted the equivalent conductivity ( $\mu$ ) of the organic radical.\* This rises very steeply in the critical region from the low value characteristic of large simple organic ions to a maximum of about

<sup>14</sup> Jones and Bury, *Phil. Mag.*, 1927, 4, 841; Grindley and Bury, *J. Chem. Soc.*, 1929, 679; Davies and Bury, *J. Chem. Soc.*, 1930, 2263.

<sup>15</sup> Hartley, "Aqueous Solutions of Paraffin-chain Salts," *Actualités Scientifiques*, Hermann, Paris. In press.

\* We use the expression "equivalent conductivity" rather than "mobility" for this quantity expressed in the ordinary units ( $\text{ohm}^{-1} \text{cm}^2 (\text{gm. equivalent})^{-1}$ ), because it has not the dimensions of a velocity per unit potential gradient or unit force. We use "radical" to signify that the property is measured for all ions of a particular kind in no matter what state of combination they occur. See Hartley and Moilliet.<sup>15</sup>

69 at a concentration of about  $N/200$ . The rise of the equivalent conductivity of this radical *above its infinite dilution value* is the most direct evidence possible<sup>1</sup> of aggregation. The *fall* of *total* equivalent conductivity during this range of concentration is due to the enormous reduction in conductivity of the bromide ions consequent on their attachment to the micelles.

This conclusion necessitates some modification of McBain's original theory of the constitution of soap solutions, which has been extended by Norris,<sup>16</sup> and McBain and Williams<sup>17</sup> to cetane sulphonic acid. The latter substance shows the critical fall of equivalent conductivity at about the same concentration as the two compounds at present under consideration.\* The mass action law makes it extremely probable that,

FIG. 3.—Equivalent conductivities of the component radicals and the whole salt, cetyltrimethylammonium bromide, 35° C.

from this concentration upwards, almost all additional paraffin-chain ions go to form micelles, and indeed it is probable that the concentration of free paraffin-chain ions decreases *absolutely*.<sup>18</sup> At a concentration of  $N/100$  it is, therefore, almost certain that there will only be a very small fraction of cetane sulphonate ions in non-aggregated forms. In McBain's composition diagram,<sup>19</sup> however, we find that the micelle is only supposed to comprise some 15 per cent. of the total even at a concentration of

<sup>16</sup> Norris, *J. Chem. Soc.*, 1922, 121, 2161.

<sup>18</sup> Murray, *Trans. Faraday Soc.*, 1935, 31, 206.

<sup>19</sup> See *International Critical Tables*, 1929, 3, 448.

$N/10$ . Micelles come into being at far lower concentrations than was thought by McBain to be the case.\*

The necessity for this modification was appreciated by Lottermoser and Püschel in their work on higher alkyl sulphates,<sup>9</sup> but these authors postulated the formation of "neutral colloid" at the critical concentration. This enabled them to postulate the formation of "ionic micelle" in higher concentrations to account for the rise of the equivalent conductivity in these concentrations (ca.  $N/20 - N/2$ ), a phenomenon which occurs in these compounds as well as in the well-known case of the soaps.<sup>20</sup> We find, however, that the first aggregates formed are by no means neutral, and that the total equivalent conductivity falls despite an *increased* mobility of the organic radical. This throws considerable doubt on the explanation of the rising conductivity, put forward by McBain and accepted by Lottermoser, as a direct effect of the replacement of a less by a more mobile form of the organic ions. It is probable that the micelles which cause a rising equivalent conductivity in methylene blue<sup>1</sup> are small. Those which, despite their high mobility, cause the steep fall of equivalent conductivity in paraffin-chain salts are probably much larger. It seems unlikely that still larger micelles (and any formed in higher concentrations must presumably be larger) would reverse the effect.

In the two salts here described, a rise of equivalent conductivity, comparable with that found in the salts with paraffin-chain anions, does not occur. The equivalent conductivity of the trimethylammonium compound (which has been investigated at higher concentrations than the pyridinium compound) does, indeed, rise slightly, above  $\cdot 3N$ , but from  $\cdot 05N$  to  $\cdot 2N$ , where the equivalent conductivity of cetane sulphonic acid rises by about 20 per cent., that of the two bromides is still falling, though very slightly. The equivalent conductivity of the *bromide radical does*, however, *rise* in this range. This gives us an important clue to what is really happening in the other salts. The almost constant equivalent conductivity in the two bromides is almost as remarkable as the rise in the case of salts of paraffin-chain anions. Analogy with ordinary electrolytes would lead us to expect a steady and fairly rapid fall. Clearly, forces are in all cases operating against those normally considered, and it seems most probable that the difference is one of degree, these forces being powerful enough to reverse the normal effect in some cases, and, in others, only to counterbalance it. Do these forces, therefore, affect the total equivalent conductivity through the contribution to it of the Gegenions? To decide this question, we must see what variation with concentration is found for the equivalent conductivities

\* Recently<sup>21</sup> McBain has concluded "most of the transition between simple crystalloid and colloidal electrolytes takes place between  $0\cdot 05$  and  $0\cdot 15N$  for undecyl and 'lauryl' ( $C_{12}$ ) sulphonic acids and in still more dilute solutions in 'myristyl' ( $C_{14}$ ) sulphonic acid." One would expect, on any theory, that further increase of chain length would lower the transition concentration still more, but McBain does not say whether his conclusions with regard to the  $C_{16}$  compound are now modified, except that "in previous diagrams boundaries should be raised by a few per cent." (italics mine—G. S. H.), nor does he make any mention of the "critical concentration" phenomena. In the earlier papers of McBain and collaborators the steep fall of equivalent conductivity in the dilute solution was attributed to extensive formation of "simple undissociated" soap (or sulphonic acid) which is a highly improbable occurrence.<sup>18</sup> It is not clear from the last paper how far this interpretation is now modified.

of the component radicals, in the case of salts which do show a rise of total equivalent conductivity.

The transport data of McBain and Bowden<sup>21</sup> for potassium oleate and laurate, of Holroyd and Rhodes<sup>22</sup> for the former salt (distinguished by \*) and of Laing<sup>23</sup> for sodium oleate, are combined in Table III. with

the conductivity figures given by McBain, Laing and Titley.<sup>24</sup> Here  $v$  denotes the equivalent conductivity of the fatty radical, and  $u$  that of the Gegenions as a whole. It will be seen that, for all these soaps, it is  $u$  which rises as  $\lambda$  rises, while  $v$ , except in the case of potassium oleate, falls. The lowest concentration of this salt, however, for which transport data are available, is already above the range in which most of the rise of  $\lambda$  occurs. In this table are given also data obtained by one of us (C. S. S., will be published in detail later) by the balanced boundary method, for cetane sulphonic acid in the range of concentrations where the very marked rise of  $\lambda$  occurs. Here there is no doubt that  $v$  falls quite rapidly while  $\lambda$  rises, and it is the great increase in the equivalent conductivity of the gegenions which causes the rise of  $\lambda$ .

It was mentioned above that McBain, and Lottermoser following him, explained the rise of total equivalent conductivity as a *direct* effect of replacement of a less by a more mobile form of the fatty ions. We see from the figures that this cannot be a generally valid explanation. The mean mobility of all the fatty ions is *not* generally increasing as the total equivalent conductivity rises. Lottermoser's explanation might, however, be *indirectly* valid. In assuming that, with increase of moderately high concentration, "neutral colloid" is replaced by "ionic micelle," he assumes that the total extent of dissociation of gegenions from micelles increases. As his "neutral colloid" cannot be quite uncharged and if his "ionic micelle" is only a little more highly charged, or present in only small amount, the increasing depression of the micelle mobilities by Debye-Hückel atmospheres might outweigh the effect of increasing charge and cause a net fall of mobility of the fatty radical. The effect

<sup>21</sup> McBain and Bowden, *J. Chem. Soc.*, 1923, 123, 2417.

<sup>22</sup> Holroyd and Rhodes, *ibid.*, 1919, 115, 1279.

<sup>23</sup> Laing, *J. Physik. Chem.*, 1924, 28, 673.

<sup>24</sup> McBain, Laing and Titley, *J. Chem. Soc.*, 1924, 125, 438.

of liberation of the gegenions, increasing the conductivity contribution of those set free from a considerably negative to a positive value, might very well outweigh any depression of the mobility of those already free, and produce the observed rise of the resultant mobility of the gegenions as a whole, and even, through this quantity, of the total equivalent conductivity.

If we consult McBain's constitution diagrams<sup>19</sup> for soaps, we see that this increase in the fraction of free gegenions (given by the combined width of the "simple fatty ion" and "ionic micelle" fields) is also implicit in his calculations. Recently, McBain and Betz<sup>20</sup> have made this same assumption explicitly and obtained valuable new evidence of its validity. They find that the osmotic coefficient (from freezing-point determinations) and "hydrogen ion activity coefficient" (from E.M.F. of cells with liquid junctions) in solutions of sulphonic acids, also increase with increase of moderately high concentrations. Lottermoser and Püschel<sup>9</sup> found a similar increase in the "silver ion activity coefficient" in solutions of silver alkyl sulphates. While the evidence from neither source is conclusive, since the Debye-Hückel contribution to the osmotic coefficient may increase without there being any change in the real degree of dissociation, and since the interpretation of cells with liquid junctions is a very difficult and uncertain procedure, particularly where very unsymmetrical electrolytes are involved, these conclusions certainly make the assumption of an increase in the fraction of free gegenions much more probable. Further suggestive evidence in the same direction is found in the peculiar variation of the alkalinity of pure soap solutions with concentration. McBain and Martin<sup>21</sup> found that the alkalinity of the concentrated solutions decreased *absolutely* with increase of concentration. This means that the fraction of acid in the undissociated form (which is presumably all contained in aggregates) decreases with increase of concentration of a solution in which the hydrogen ion concentration is *increasing*.<sup>\*</sup> The micelles can, therefore, lose hydrogen ions despite the increase in the bulk concentration of the latter, and it is, therefore, probable that other cations can also be liberated under similar apparently unsuitable conditions.

It seems difficult to account for the fact that the rise of total equivalent conductivity is caused by a rise of that of the gegenions, as a whole, and not by a rise of that of the fatty radical, in any other way than by liberation of gegenions from the micelles. We must not, however, lose sight of the fact that, in a solution where the mobility of the gegenions is low because many of them are carried backwards by micelles, a fall in the mobility of the micelles will produce, in the absence of any other changes, a rise in that of the gegenions. In a solution where micelles of diverse sizes are present, it does not seem obvious what the effect on the total equivalent conductivity may be. In a more detailed discussion in the third section, we come, however, to the conclusion that the conductivity and transport data for cetane sulphonic acid do almost certainly necessitate the assumption that gegenions are re-liberated, whether one or two fundamental types of micelle, each comprising a range of minor

<sup>19</sup> McBain and Betz, *J. Amer. Chem. Soc.*, 1935, **57**, 1909, 1913.

<sup>20</sup> McBain and Martin, *J. Chem. Soc.*, 1914, 105, 957.

<sup>\*</sup> This is the important difference from the case of the hydrolysis of the salt of a simple weak acid. In the latter the fraction of acid in the undissociated form also decreases with increase of concentration, but so does the concentration of hydrogen ions.

variations, is assumed. This being so, it seems to us unnecessary to assume, as Lottermoser does, the existence of two different types.\* May not the re-liberation of gegenions be just as likely an effect of concentration on micelles of essentially the same type? We are not wholly without a plausible physical picture of such a concentration effect. The fraction of the gegenions which adhere to the micelle will be governed mainly by their concentration in the free state near its surface. This will be greater than their concentration in bulk, and the factor by which the latter must be multiplied to give the former, which may be obtained approximately by graphical integration of the Boltzmann-Poisson equation, decreases with increase of concentration.<sup>3</sup> For large micelles this decrease is so great as to make the concentration of gegenions near the surface of the micelle *tend* towards a *constant* value. It is not, therefore, difficult to understand that the fraction of free gegenions will *not decrease* very rapidly. These conclusions are based on the picture of a spherically symmetrical atmosphere around the micelle. For two reasons this picture is seriously incomplete. First, the charges on the micelle are at discrete points, fairly far apart, and the near portions of the atmosphere will, therefore, collect, as it were, into nodules. Secondly, the occasional near-approaches of micelles to one another will produce temporary distortions which cannot be averaged out in any simple way. It is only necessary for these distortions to have more effect in reducing the atmosphere concentration at some times and places than in increasing it at others to give us a mechanism for the decrease of the number of gegenions attached to each micelle.

## II. General Relationships Between Conductivities in a Solution Containing Micelles, not all of one Kind.

Before making a closer examination of the rising equivalent conductivity or attempting to form some estimate of the size of the micelles formed in dilute solutions, it will be necessary to derive certain fundamental equations relating the various equivalent conductivities.

The nomenclature and definitions of Hartley and Moilliet<sup>12</sup> will be used, but we shall replace the symbol  $f$  of Hartley and Robinson<sup>27</sup> by  $\theta$ , in order that in later papers the former symbol may be used without confusion for the activity coefficient, in accordance with general usage.

Let a fraction  $x_p$  of all the paraffin-chain ions in solution exist in the form of micelles of type P, each containing  $m_p$  paraffin-chain ions with  $n_p$  gegenions adhering to them. Let the mobility of the micelle (its mean velocity in cms./sec. in a field of 1 volt/cm.) be  $L_p$ . The contribution made by the paraffin-chain ions in the form of this micelle to the total specific conductivity will be  $cx_p L_p F$  where  $C$  is the total equivalent concentration (equivalents per c.c.) and  $F$  is the Faraday number in coulombs. Replacing the product  $L_p F$  by  $l_p$ , the latter being the *equivalent conductivity* of paraffin-chain ions in micelles of type P, and dividing by  $c$ , we get, for the contribution which the paraffin-chain ions in these micelles make to the total equivalent conductivity,  $x_p l_p$ . If we assume the whole of the paraffin-chain ions to be included in this treatment (i.e., confine ourselves, as we shall do, to the concentrations where

\* McBain's argument for the existence of two types of colloidal particle was based on other data, and is referred to in the last section.

<sup>27</sup> Hartley and Robinson, *Proc. Roy. Soc.*, 1931, 134A, 20.

only a negligible fraction of them exist in simple form \*) the equivalent conductivity of the paraffin-chain radical ( $u$ ) will be given by

$$u = \sum_p x_p l_p \quad (2)$$

Now, if the fraction  $(m_p \cdot n_p)/m_p$  be written as  $\theta_p$ , the total concentration of free gegenions will be  $\sum_p x_p \theta_p$ , and the contribution of these to the equivalent conductivity will be  $l_g \cdot \sum_p x_p \theta_p$  where  $l_g$  is the equivalent conductivity of free gegenions. The concentration of the gegenions present in the form of micelles of type P is  $cx_p(1 - \theta_p)$ , and as these have a mobility of  $L_p$ , which is *negative* for the gegenions, the contribution of the gegenions as a whole to the total equivalent conductivity, will be

$$v = l_g \cdot \sum_p x_p \theta_p - \sum_p [x_p(1 - \theta_p)l_p] \quad (3)$$

The total equivalent conductivity is, of course, the sum of (2) and (3), *i.e.*

$$\lambda = l_g \sum_p x_p \theta_p + \sum_p x_p l_p \theta_p \quad (4)$$

and the transport numbers are the quotients of (2) and (3) by (4). The conductivity and transport measurements are thus completely represented by these two equations. It will be convenient, however, to introduce average values of  $\theta$ ,  $l$  and  $l\theta$  which will be given by

$$\bar{\theta} = \sum_p x_p \theta_p \quad (5)$$

$$\bar{l} = \sum_p x_p l_p \quad (6)$$

$$\bar{l}\bar{\theta} = \sum_p x_p l_p \theta_p \quad (7)$$

a - denoting a mean quantity.  $\bar{\theta}$  measures the total degree of dissociation of gegenions. Equations (2) and (4) now become—

$$u = \bar{l} \quad (8)$$

$$v = l_g \bar{\theta} - \bar{l} + \bar{l}\bar{\theta} \quad (9)$$

$$\lambda = l_g \bar{\theta} + \bar{l}\bar{\theta} \quad (10)$$

If we were dealing with only one type of micelle, the mean values would be single values and, therefore,  $\bar{l}\bar{\theta}$  would be equal to the product of  $\bar{l}$  and  $\bar{\theta}$ . In general, however, this will not be true, and it will be useful for the purpose of analysis to separate the effects of change of average properties from change of "diversity" or "fluctuation" about the average. This can be done by introducing a function  $\chi$ , defined by the equation

$$\bar{l}\bar{\theta} = \chi \cdot \bar{l} \cdot \bar{\theta} \quad (11)$$

which represents specifically the effect of this fluctuation,  $\chi$  being unity for zero fluctuation and greater or less than unity according to the way in which the fluctuations of  $l$  and  $\theta$  are related. Substitution of (11) in (10) gives us

$$\lambda = l_g \bar{\theta} + \chi \cdot \bar{l} \cdot \bar{\theta} \quad (12)$$

and of (11) in (9) gives

$$v = l_g \bar{\theta} + \bar{l}(\chi \bar{\theta} - 1) \quad (13)$$

\* Strictly, this treatment is in any case quite general because one kind of "micelle" can be considered to be the simple paraffin-chain ion and another kind the simple ion-pair.

Solving (12) and (8) for  $\bar{\theta}$ , we obtain

$$\bar{\theta} = \frac{\lambda}{l_0 + \chi u} \quad (14)$$

These equations are exact. It remains to be considered what conclusions may be drawn from them on certain assumptions.

### III. Further Considerations of the Increase of Equivalent Conductivity with Concentration.

Consideration of equations (8) and (12) shows that the value of  $d\lambda/dc$  can only be positive while  $du/dc$  is negative if  $dl_0/dc$ ,  $d\bar{\theta}/dc$  or  $d\chi/dc$  are one, two or all positive. The first two possibilities, an increase with concentration in the mobility of the free gegenions, or an increase in their total degree of dissociation, are quite contrary to expectations based on a knowledge of simple electrolytes. One or both of these increases must occur, however, unless  $d\chi/dc$  is not only positive, but sufficiently great for  $d(\chi u)/dc$  to be positive.

Now, in cetane sulphonic acid, from 0.046*N* to 0.162*N*,  $v$  (which interchanges throughout with  $u$  for cases where the paraffin-chain has an anionic end group) decreases by 32 per cent.,  $\chi$  would, therefore, have to increase by 46 per cent. even to maintain  $\lambda$  constant, and if neither  $\bar{\theta}$  nor  $l_0$  decreased. To produce the observed rise of  $\lambda$  by 18 per cent., the increase of  $\chi$  would have to be much greater still. Even if the function  $\chi$  changes in the desired direction, is a change of this magnitude at all probable?

It is evident, from the definition of  $\chi$  (equation (11)), that, if the  $l$  and  $\theta$  values of the various micelles were *entirely* independent,  $\chi$  would be unity. The variations will not, however, be entirely independent. If another gegenion attaches itself to a micelle which suffers no other change, *both*  $l$  and  $\theta$  will be decreased, and approximately proportionally, since the radius of the micelle is not appreciably altered. If another paraffin-chain ion enters while the number of gegenions remains the same, we shall have an increase of  $\theta$ . The charge of the micelle will be increased, relatively, much more than its radius, and  $l$  will, therefore, be increased also. Since the volume of the micelle will consist almost entirely of paraffin-chain ions, it will be proportional to  $m$  and its effective radius, therefore, to  $m^{1/3}$ , while its charge will be given by  $m\theta$ . We shall, therefore, have, roughly,  $l \propto m^{1/3} \cdot \theta$ , and the second change of composition mentioned, since it increases  $m$  and  $\theta$ , will give an increase of  $l$  relatively greater than that of  $\theta$ . Addition or removal, however, of ions of either kind independently of the other, will not occur to any considerable extent. If  $m$  increases without increase of  $n$ , the potential at the surface of the micelle will increase and gegenions will, therefore, close in on the micelle and an increase of  $n$  with consequent decrease of  $\theta$  is almost certain to follow. Similarly, a decrease of  $m$  will result in an increase of  $\theta$ . For micelles of essentially the same type, i.e. micelles formed by aggregation of the paraffin chain ions in some definite state (isotropic liquid, nematic liquid, crystalline solid, etc.), the tendency will be for a certain constant potential to be maintained. Potential and mobility are approximately proportional, both being approximately proportional to  $m^{1/3} \cdot \theta$ , and hence the *tendency* will be for  $l$  to have a constant value for all the micelles of the same fundamental type at any one concentration,

just as the much larger particles of an ordinary colloid have mobilities almost independent of size.

On the whole, therefore, what variations of  $l$  and  $\theta$  occur will be sybantic, *i.e.* we are more likely to find the high  $l$  values among the high  $\theta$  values than among the low ones, and the low  $l$  values among the low  $\theta$  values than among the high ones. Variation of this type will make the high values relatively more important in the  $l\theta$  products than in  $l$  and  $\theta$  separately, so that the mean of the products will be greater than the product of the mean values, *i.e.*,  $\chi$  will be  $> 1$ . Since, however,  $l$  will vary less than  $\theta$ , the difference of these mean values will be less than it would be if  $l$  varied proportionally with  $\theta$ , *i.e.*,  $\chi$  will be  $< \bar{\theta}^2/(\bar{\theta})^2$ .

We should not be justified in attempting any statistical treatment of the  $\theta$  variations until we know far more than at present about the forces involved. We think, however, that it will be generally agreed that the case where one-third of the micelles have  $\theta$  values equal to the mean, one-third values half as great, and one-third values one-and-a-half times as great, though of a very artificial kind, represents far greater fluctuation than is at all likely to occur. For this case,

$$\bar{\theta}^2/(\bar{\theta})^2 = \frac{1}{3}\left[\left(\frac{1}{2}\right)^2 + 1^2 + \left(\frac{3}{2}\right)^2\right] = 7/6.$$

The extreme probable limits of  $\chi$  are thus seen to be very close together, the lower limit being 1 and the upper limit being almost certainly  $< 1.1$ .

Increase of  $\chi$  by more than 46 per cent. is thus quite out of the question if we have micelles of fundamentally a single type.

Can the possible existence of two fundamentally different types of micelle enable us to avoid the conclusion that  $d\bar{\theta}/dc$  (or  $dl_g/dc$ ) is positive? Suppose we have two types, A and B. We shall distinguish quantities pertaining to each by suffixes  $a$  and  $b$ , and denote the fraction of paraffin-chain ions in the form of B micelles by  $y$ . We shall consider that it is the B micelles which increase at the expense of A micelles as the concentration increases (*i.e.*,  $dy/dc$  positive). In place of (8) and (12) we shall now have

$$u = l_a \cdot (1 - y) + l_b \cdot y \quad (15)$$

and

$$\lambda = l_g \bar{\theta} + \chi_a l_a \bar{\theta}_a \cdot (1 - y) + \chi_b l_b \bar{\theta}_b \cdot y \quad (16)$$

Now, if we are to avoid assumptions of the same kind of apparent improbability as positive values of  $d\bar{\theta}/dc$  and  $dl_g/dc$ , we must assume not only these quantities to be negative, but all  $d\bar{\theta}/dc$  and  $dl/dc$  values to be also negative and  $\bar{\theta}_b$  to be  $< \bar{\theta}_a$ .

If we write

$$G = l_g \bar{\theta} + l_a \bar{\theta}_a (1 - y) + l_b \bar{\theta}_b y \quad (17)$$

then, since the  $\chi$  values must be between 1 and  $\chi_{\max.}$ , where  $\chi_{\max.}$  is their highest possible value, we have

$$\lambda > G \quad (18)$$

and

$$\lambda < \chi_{\max.} \cdot G - (\chi_{\max.} - 1) l_g \bar{\theta}. \quad (19)$$

Differentiating (17) with respect to concentration,

$$\frac{dG}{dc} = l_g \frac{d\bar{\theta}}{dc} + \bar{\theta} \frac{dl_g}{dc} + \bar{\theta}_a \frac{d}{dc} [l_a (1 - y)] + \bar{\theta}_b \frac{d}{dc} (l_b y).$$

the aggregates are essentially liquid,<sup>15</sup> and since they will tend to present the minimum surface (which cannot consist entirely of "heads") to the water, they will presumably be roughly spherical and of the largest radius consistent with none of the "heads" being submerged in the paraffin interior. The radius of the paraffin centre will be slightly less than the length of a single fully-extended chain. For a chain of 16 C atoms this length will be about 19.2 Å, and the radius of the paraffin centre can, therefore, be taken as about 18 Å. From the volume of this, and taking the density to be that of liquid cetane (0.77), we can obtain the number of cetyl chains contained, which comes to about 50. In calculating the mobility of this micelle, we must make some allowance for the effective thickness of the ionic "heads" for which we may allow about 3 Å. The Stokes' law (without atmosphere effect) equivalent conductivity of paraffin-chain ions in this micelle at 35° C. will be  $276 \times \bar{\theta}$ ,  $\bar{\theta}$  having the significance previously described.

Let us take the case of cetyltrimethyl-ammonium bromide at a concentration of  $N/50$ .  $\lambda$  is = 33, and  $u = 53.5$ . If we assume  $l_0$  to be reduced by about 25 per cent. by atmosphere effects, its value becomes 71. Taking a probable value for  $\chi = 1.05$ , and substituting in equation (14), we obtain  $\bar{\theta} = 0.26$ . The average charge on the micelle is, therefore,  $50 \times 0.26 = 13$ , and the solution is, therefore, to be considered as a 1.13-valent electrolyte of concentration  $0.02 \times 0.26 = 0.0052N$ . For this the value of  $1/\kappa$  (the thickness of the atmosphere in the simple Debye-Hückel theory) comes to 16 Å.  $a$ , the distance of closest approach of the centres of a micelle and a gegenion, can be taken as 22 Å. Now, according to the simple Onsager assumptions, the "endosmotic" contribution to the equivalent conductivity of the micelle would reduce it to  $\frac{1}{1 + \kappa a}$  of its Stokes' law value.<sup>9</sup> The Stokes' law value is  $276 \times 0.26 = 72$ , and this would, therefore, be reduced to 30 instead of the observed 53. Although the reduction predicted by the simple theory is probably too great, reduction from 72 to 53 only by atmosphere effects is probably too small. We shall probably have, therefore, a higher value for  $\bar{\theta}$  which can only be obtained by taking a lower value, say 50, for  $l_0$ . This would give us  $\bar{\theta} = .31$ , valence of the micelle = 15.5,  $1/\kappa = 13.5$  Å, and a Stokes' law value of  $u = 86$ . The latter would be reduced by the endosmotic term of the simple theory to 33. The observed reduction to 53 is now probably not too much less than that which the simple theory predicts.

Taking, now, the figures for the  $N/10$  solution, we have  $\lambda = 29$ , and  $u = 40$ . If  $l_0$  is now further reduced to, say, 40,  $\bar{\theta}$  becomes 0.35, valence of micelle = 17.5,  $1/\kappa = 5.4$  Å, and Stokes' law value of  $u = 97$ . The latter would be reduced, according to the simple theory, to so low a figure as 19, and it is not, therefore, surprising that the observed value of 40 is less than in the  $N/50$  solution despite the increase of Stokes' law value consequent on the re-liberation of some of the adherent gegenions.

The least satisfactory feature of these calculations is the low values of  $l_0$  which have to be assumed in order to avoid an improbably small value of the atmosphere reduction of micelle mobility. Until we have a satisfactory theoretical method of estimating the velocities of small ions near to large and highly-charged ones, it would not be useful to discuss the ways in which this difficulty could be avoided, except to mention that the assumption of a still larger micelle (which would have

to be ellipsoidal) is one of them. As Henry<sup>28</sup> has pointed out, a correction to the Stokes' law equation should be made for large particles which are internally non-conducting: for sufficiently large particles, this correction replaces the 6 in the denominator of the Stokes' expression for velocity by 4: this is in the right direction to reduce our difficulty, but it does not seem probable from Henry's calculations that our micelles are sufficiently large for the correction to be important.

It is hoped that, when accurate thermodynamic data are available for the dilute solutions, the size of the micelle may be more definitely estimated. Since the micelles will exert but little osmotic effect, the osmotic pressure, freezing-point depression, etc., will be due mainly to the free gegenions. There will, of course, be a considerable influence of ionic atmospheres which, however, can probably be more confidently estimated than the influence on the mobilities. If the osmotic coefficient, due to atmosphere effects, is  $g$ , then the observed van't Hoff factor,  $i$ , will be equal approximately to  $g\bar{\theta}$ . It is of interest to note that McBain, Laing and Titley<sup>24</sup> found the value of  $i$ , at 0° C., in the most dilute solutions of potassium oleate which they investigated, namely 0.2  $N$ , to be 0.32. This is quite comparable with the value which we found probable for  $\bar{\theta}$  at 0.1  $N$ , in the case of cetyltrimethylammonium bromide. Work on other salts is in progress, and we hope to obtain more definite information also from comparison of the behaviour of salts having gegenions of different mobility and valence.

Finally, we may refer to the question of whether there is any conclusive evidence for the existence of more than one type of micelle. The fundamental argument by which McBain<sup>21</sup> concluded that two types must be present, rested on the comparison of conductivity, transport and freezing-point data. It may be very conveniently expressed in terms of the general equations derived above. If we assume, as McBain did, that atmosphere effects are negligible, we can substitute  $i$  for  $\bar{\theta}$  in equation (14), and take  $l_0$  to have its value at infinite dilution. We may then calculate the value of  $\chi$ . Taking values obtained directly, or by interpolation, from the work of McBain and collaborators,<sup>21, 24</sup> we have, for potassium oleate at 0.2  $N$ ,  $\lambda = 33.3$ ,  $T_{01} = 0.78$  (both at 18° C.) and  $i = 0.32$  (at 0° C.), whence  $\chi$  must be = 1.5. At 0.5  $N$ ,  $\lambda = 37.0$ ,  $T_{01} = 0.70$  (at 18° C.) and  $i = 0.32$  (at 0° C.), whence  $\chi$  must be 2.3. If we have  $\chi$  values really as high as these, the  $l$  and  $\theta$  values of the various micelles present must be symbatic, and the variations must be so great that they could only be accounted for by micelles of fundamentally different types existing together, "ionic micelles" having high  $l$  and  $\theta$  values, and "neutral colloid," having very low values of  $l$  and  $\theta$ . Several factors, however, make the argument inconclusive. In the first place, there is a discrepancy in temperature between the measurements.  $i$  is known to increase with temperature,<sup>24</sup> and, if it is only 10 per cent. higher at 18° C. than at 0° C., the values of  $\chi$  become 1.1 and 1.8, so sensitive are they to the value of  $i$ . In the second place, the atmosphere effects must be considered. We should replace  $\bar{\theta}$  in (14) by  $i/g$  rather than  $i$ , and assign to  $l_0$  a much lower value than that at infinite dilution. If we took the latter to be 40 for 0.2  $N$  and 30 for 0.5  $N$  in place of the infinite dilution value of 65, we should increase considerably the values of  $\chi$ , but it would only be necessary for the values of  $g$  to be 0.71 and 0.51 respectively for  $\chi$  to be reduced to 1.05, a value which it could have

<sup>28</sup> Henry, *Proc. Roy. Soc.*, 1931, 133A, 106.

## 814 TRANSPORT NUMBERS OF PARAFFIN-CHAIN SALTS

if only one type of micelle were present. Such values of  $g$  are by no means inconceivable. If we apply the extended formula of Debye and Hückel,<sup>29</sup>

$$1 - g = - \frac{1}{4\pi a^2 \sum n_i} \left[ \log_e (1 + \kappa a) - \frac{\kappa a}{2(1 + \kappa a)} - \frac{\kappa a}{2} \right] \quad (15)$$

where  $\sum n_i$  is the total number of charged particles per c.c., to evaluate  $g$  for the case of a 1-20 valent electrolyte having an " $a$ " value of 20 Å, we obtain the values of 0.68 and 0.77 for 0.1*N* and 0.25*N* solutions, these concentrations being taken because they will be nearer to the effective concentration of the soap solution, which is the stoichiometric concentration multiplied by  $\bar{\theta}$ . In an attempt to estimate more correct values for the various coefficients than the simple Debye-Hückel theory is likely to give, one of us (G. S. H.)<sup>3</sup> came to the conclusion that the correct values for  $g$  are probably *higher* than those given by equation (15). His calculations, however, were not made for higher concentrations than  $N/100$ , and it would, indeed, be quite worthless to attempt at present any computations for concentrations as high as those for which data are at present available. It is well to appreciate how concentrated these solutions are: the micelles carrying the enormous charge of perhaps 30, are about 40 Å in diameter and their mean distance apart, centre to centre, is only about 58 Å in the 0.5*N* solution. The application of the Debye-Hückel theory to such a system can only at present leave us with enormous uncertainty. These calculations have been introduced here chiefly to show how very much more seriously than is sometimes realised \* the considerations of "atmosphere" effects can influence the quantitative arguments, and to show that the simple picture of these solutions derived from consideration of the causes underlying their peculiar behaviour is probably quite adequate to explain all the measured properties. If any evidence is to be conclusive on this question of the existence of more than one type of colloidal particle, it must depend on properties uninfluenced by coulomb forces. It is hoped in the near future to present results of measurements of some such properties.

<sup>29</sup> See Falkenhagen, *Elektrolyte*, 253 (Leipzig, 1932).

\* McBain has frequently expressed the opinion<sup>17, 20, 21</sup> that, since the charges on the surface of the micelle are far apart (the mean distance apart of thirty free charges on a micelle of radius 20 Å is about 13 Å, which is rather greater than the mean distance apart of like ions in a 0.75*N* solution of a uni-uni-valent electrolyte) the charge of the micelle is not a concentrated one, and the atmosphere effects, therefore, likely to be little greater than in a simple electrolyte. This argument has not been supported by any detailed considerations. As far as the atmosphere of the micelle as a whole is concerned, the charge, since it will be uniformly distributed, can be considered to behave as though concentrated at the centre. The size of the micelle is then fully allowed for by considering the atmosphere to extend inwards only up to a shell 20 Å away from this centre: it is true that the field of force here is no greater than near some simple ions, but it is *much more extensive*, both radially and tangentially, and detailed considerations<sup>3</sup> show that this leads to the existence of enormously greater atmosphere effects. Now it is true that, near the micelle, the atmosphere will be localised around the individual ions in the surface, but the effect of this will be *added* to that of the micelle as a whole. The effect of the centre of the micelle having a very low dielectric constant can again only increase the effects above what is predicted assuming only the dielectric constant of water to be relevant.

<sup>20</sup> McBain, *J. Amer. Chem. Soc.*, 1928, **50**, 1636.

### Summary.

1. Measurements have been made of the equivalent conductivity and transport numbers of two salts with paraffin-chain *cations*, containing 16 C atoms in the chain with the cationic group at the end. The results of a few measurements on cetane sulphonic acid are also recorded, and data collected from the literature on soaps are given for comparison.

2. The transport number of the paraffin-chain radical rises very rapidly with increase of concentration in the range, commencing abruptly at about  $N/1000$ , where the total equivalent conductivity falls, and attains values considerably greater than unity. In the first part of this range the rise of transport number is so great that the equivalent conductivity of the paraffin-chain radical rises above its value at infinite dilution, a fact which provides conclusive evidence of the formation in this range of mobile micelles—aggregates of paraffin-chain ions.

3. That a *fall* of total equivalent conductivity occurs when the micelles form is due to their great depressant effect on the mobility of the bromide ions, by causing some of these to adhere to them and exercising a braking influence on the others. The mean mobility of the bromide ions as a whole is negative over a considerable range of concentration.

4. The equivalent conductivity of the paraffin-chain radical reaches a maximum before the total equivalent conductivity has ceased its steep fall, and continues to fall while the latter is almost constant. In other paraffin-chain salts in which the total equivalent conductivity rises again in the moderately concentrated solutions, that of the paraffin-chain radical also falls. The rise of the total equivalent conductivity cannot, therefore, be due, as it has been thought to be, directly to replacement of less mobile simple ions by more mobile micelles. It is almost certainly due to the micelles, which have already been formed in much lower concentrations, re-liberating some of their attached gegenions. It does not seem necessary to assume the existence of more than one type of micelle.

5. Owing to the uncertainty of coulomb force effects of the Debye-Hückel type, it is not possible at present to draw any definite conclusions about the size of the micelles, except between limits so wide as to be hardly worth discussion, but roughly spherical micelles of about 20 Å radius, and containing about 50 paraffin-chain ions, whose existence is suggested by consideration of the forces operating in micelle formation, could not unreasonably explain the measured properties of the solutions.

One of us (B. C.) took part in this research at the suggestion of Dr. Conmar Robinson, and his contribution was made during the tenure of a Yuill scholarship of the University of Aberdeen, to whom our thanks are due. We are indebted to Dr. Robinson for the great interest he has taken in this work. Some of the work of C. S. S. was done during the tenure of a grant from the Department of Scientific and Industrial Research, for which we should also like to express thanks.

# PROPERTIES OF ILLUMINATED IODINE SOLUTIONS. PART II.—THE NEGATIVE ABSORPTION EFFECT IN BENZENE AND OTHER SOLVENTS.

BY E. RABINOWITCH AND W. C. WOOD.

Received 21st February, 1936.

In a previous paper<sup>1</sup> we described the reversible *decrease* in the extinction-coefficient of illuminated iodine solutions in carbon tetrachloride and hexane caused by intense illumination and showed that this effect can be quantitatively accounted for by assuming a shifting of the equilibrium between  $I_2$  molecules and I atoms, due to light absorption. We showed that in a number of solutions, including those of iodine in  $C_6H_6$ ,  $CH_3OH$ , and  $H_2O$ , and probably also that of bromine in  $CCl_4$ , the effect has an opposite sign—the extinction-coefficient *increases* by illumination. We now describe some quantitative experiments made with benzene, and try to find an adequate explanation of the results obtained. The experimental arrangement was the same as that described in our previous communication.

## Experimental Results.

Fig. 1 shows a set of measurements, made with a solution containing  $4.0 \times 10^{-5}$  gram molecules  $I_2$  per litre of benzene. The ordinates are readings of the galvanometer, indicating the intensity of the light passing the absorption-cell filled with the solution; points indicate that the cell

FIG. 1.

was kept in the dark, circles that it was uniformly illuminated by a 25 amps. carbon arc. The transmission is seen to be *smaller* during the illumination. The negative effect in  $C_6H_6$  is about five times greater than the positive effect in carbon tetrachloride under the same conditions of concentration and light intensity (*cf.* Fig. 2 in Paper I.). At the highest light intensities used ( $5 \times 10^{18}$  quanta absorbed per second in 1 c.c. of solution) the relative

<sup>1</sup> *Trans. Faraday Soc.*, 1936, **32**, 547.

change in the extinction-coefficient of the illuminated solution was of the order of 0.05 per cent.

(a) **Dependence of the Effect on Light Intensity.**—Table I. shows the results obtained, at constant  $I_2$  concentrations, by variation of the intensity  $L$  of the illumination. A comparison of the last two columns of Table I. shows clearly that the negative effect is *proportional to the square root of the light intensity*—a rule which was found to hold in the case of the positive effect as well.

TABLE I.

Exp.	$c(I_2) \times 10^4$ mols./l.	$L$	$\Delta I$	$\frac{\Delta I}{L}$	$\frac{\Delta I}{\sqrt{L}}$
100	4.0	44	— 22.7	0.52	3.42
		27	— 18.6	0.63	3.58
		17.5	— 16.2	0.93	3.88
		9.5	— 11.5	1.21	3.74
	8.0	32	— 16.7	0.52	2.96
		13.5	— 11.1	0.83	3.00
		9.0	— 8.2	0.91	2.73
	120	43	— 32.5	0.72	4.95
		25	— 25.8	1.03	5.16
		14	— 17.4	1.24	4.65
		9.5	— 14.1	1.48	4.57
		9.0	— 13.8	1.53	4.00

(b) **Dependence of the Effect upon the Concentration of Iodine.**—Since different concentrations mean different values  $I$  of the total light transmitted by the solution, we have to compare the *relative* changes of transmission  $\Delta I/I$  corresponding to a given light intensity  $L$ . We use (in Table II.) for this purpose the mean values of  $\Delta I/\sqrt{L}$  deduced from exp. 100 in Table I. The last two columns of Table II. indicate that the negative effect (in common with the positive effect) is proportional with the *square root* of the iodine concentration. The dependence of the effect on  $I_2$  concentration is completely accounted for by the corresponding change in absorption, since the number of quanta absorbed is roughly proportional to the concentration. For a constant number of quanta absorbed the effect is *independent of the iodine concentration*.

TABLE II.

$c(I_2) \times 10^4$	$\frac{\Delta I}{\sqrt{L}}$	$I$	$\frac{\Delta I}{I\sqrt{L}}$	$\frac{\Delta I}{I\sqrt{L}c}$
4.0	3.66	7.4	0.12	0.25
8.0	2.90	3.9	0.09	0.26

(c) **Influence of the Wave-Length of the Illuminating Light.**—Experiments were made with the three sets of filters described in Paper I. which properties are given in Table III. The extinction-coefficients for set 2 and, especially, set 1 are somewhat higher than in the case of the iodine solution in  $CCl_4$  (470 and 750 instead of 325 and 625) corresponding to the differences

in the extinction curves of these two solutions. The results obtained in these three spectral regions are given in Table IV. The last column shows

TABLE III.

Filter-Set.	Region.	$\bar{\lambda}^*$ .	$\bar{\epsilon}^*$ .
1	4000-5000 Å.	4700 Å.	470
2	4000-5500 Å.	5000 Å.	750
3	5000-5800 Å.	5700 Å.	550

TABLE IV.

$\bar{\lambda}$ .	$L$ .	$\Delta I$ .	$\Delta I \sqrt{\frac{\bar{\lambda}^*}{L \epsilon^*}}$ .
4700 Å.	10	6.4	6.4
5000 Å.	32	16.7	7.6
5400 Å.	30.5	13.4	7.9

$\bar{\lambda}^*$  and  $\bar{\epsilon}^*$  are the mean wave-length and the mean extinction-coefficient of the illuminating light;  $\bar{\lambda}$  and  $\bar{\epsilon}$  (in Table V.) meaning the same quantities for the photo-cell light.

that, for the same number of quanta absorbed, the effect remains unchanged throughout the spectral region concerned; at least there is definitely no decrease in the effect in the long-wave length region, above the convergency limit of  $I_2$  gas at 4990 Å. This was also valid for the positive effect. If the first stage of the process is formation of iodine atoms, we must admit that the quantum yield of this dissociation process in benzene solution is the same below and above the convergency limit.

(d) **The Effect in Different Spectral Regions.**—The positive effect is due to the disappearance of a part of the  $I_2$  molecules, and there is no reason to expect a dependence of this effect on the wave-length of the light used for the measurement of the extinction-coefficient. The negative effect, however, must be due to the formation of some light-absorbing substance during illumination; the extinction curve of this unknown substance may be very different from that of the original solution. We therefore experimented with a constant concentration of iodine, and the same illuminating light, but different light-filters in the path of the beam used for the measurement of the extinction. The results are collected in Table V. These measurements although very rough (because of the wide

TABLE V.

spectral regions used) clearly indicate a *decrease* in the quantity  $\frac{\Delta I}{I_0 \sqrt{L}}$  with increasing wave-length. If the negative effects were due to a simple *increase in concentration* of the  $I_0$  solution (as the positive effect is due to a *decrease* in it), then this quantity must be constant. The result indicates therefore that the absorbing molecules produced by illumination are *different from those forming the original solution*.

We will call this unknown substance the "photo-complex." If the photo-complexes were formed from a material which does not itself absorb visible light (i.e., if the negative and positive effects were not combined), then the numbers in the penultimate column of Table V. would be simply proportional to the extinction-coefficients of the photo-complex. The extinction-curve would be that shown in Fig. 2. Since it is more probable that the photo-complex is formed at the cost of the original absorbing substance, the extinction-coefficients shown in Fig. 2 must be augmented by certain values proportional to the extinction-coefficients of the original solution.\*\* This uncertainty cannot, however, change the general shape of the extinction-curve shown in Fig. 2. The photo-complex thus differs from the original  $I_0$  solution by its relatively stronger absorption on the short wave-length side of the absorption-maximum.

(e) **Dependence of the Effect on Benzene Concentration.**—Table VI. shows the effect as a function of the concentration of benzene in carbon tetrachloride as a "neutral" solvent. The first value in the last column is very uncertain, because the effect passes through zero near this concentration. The last three values indicate that the resulting effect

FIG. 2

TABLE VI.

$$c(I_0) = 8 \times 10^{-4} \text{ mols./l.}$$

$[C_6H_6]$ Vol. per Cent.	$L$	$\Delta I$	$\frac{\Delta I}{\sqrt{L}}$	$\frac{\Delta I}{\sqrt{L} - 0.3} \cdot \frac{1}{[C_6H_6]}$
0	41	+ 3.2	+ 0.5	—
2	27	+ 1.2	+ 0.23	(0.14)
16.7	34	— 1.2	— 0.17	0.040
50	33	— 6.3	— 1.10	0.032
100	32	— 16.7	— 2.90	0.035

\*\* The factor of proportionality depending upon how many molecules of the photo-complex are formed at the cost of one molecule of the original substance.

is a linear function of the composition of the solution. In all probability, the negative effect by itself is simply proportional to the benzene concentration.

(f) **Effect in Benzene Vapour.**—No negative effect was observed in a mixture of iodine-vapour ( $p = 0.16$  mm., corresponding to  $c = 1 \times 10^{-4}$  mols./litre), with benzene vapour ( $p = 75$  mm., corresponding to  $c = 4.5 \times 10^{-3}$  mols./litre). This concentration is, however, still much lower than the smallest benzene concentration at which the negative effect was observed in solution ( $c = 1.5$  mols./l).

(g) **Effects in Other Solvents.**—A negative effect of the same order of magnitude as in benzene was observed in a saturated iodine solution in water and in a solution of iodine in methyl-alcohol. A very small negative effect was observed in a *bromine* solution in carbon tetrachloride, but this result remains rather uncertain.

### Discussion.

The following facts require an explanation :—

The occurrence of the negative effect.

Its proportionality with the square root of the light energy absorbed.

Its independence of the iodine concentration (other than that required by the foregoing point).

Its proportionality with the benzene concentration.

Two possible explanations are :—

(1) To assume the *dissociation by light of some complexes existing in the original solution*, and formation of free iodine, the process being reversed in the dark.

(2) To assume the *formation of complexes* (or increase in the concentration of already existing complexes), which dissociate again in the dark.

(1) **Dissociation of Complexes.**—This explanation is suggested by the fact that the negative effect is exhibited by solutions which are known to contain solvates ("brown" and "red" iodine solutions), and not by "violet" solutions in which the greater part, at least, of the iodine is in the form of free  $I_2$  molecules. It is conceivable that these complexes absorb more strongly in the ultra-violet than in the visible region and their destruction may therefore lead to an increase in the extinction coefficients in the visible region.

The difficulties of this explanation are, however, very great : (a) The absorption-curve of the "photo-complex" appears, according to Fig. 2, to be different from that of "free" iodine. (b) The proportionality of the effect to the *square root* of the light intensity can be explained only on the assumption that the destruction of the complexes is achieved by iodine atoms, e.g., by a mechanism of the following kind :—

A mechanism of this kind is not impossible in itself, but the number of complexes destroyed during their life-time by iodine atoms must be proportional to the concentration of these complexes, and thus to the concentration (or some power of the concentration) of the iodine in solution, whereas the experiment shows no dependence of the effect on the iodine concentration. (c) In order to account for the order of magnitude of the effect, it is necessary to assume the formation of the complexes to be a *slow* process. The assumption that an activation energy is necessary for the formation of a solvate is, however, very unusual. The Van

der Waals forces, which are supposed to account for the formation of solvates, are purely attractive and cannot give rise to a potential barrier.

(2) **Formation of Complexes.**—The complexes in question can involve either iodine-atoms or molecules. In order to fulfil the square root law, the complexes must either be formed with a velocity proportional to the square root of the light intensity (and dissociate *mono-molecularly*), or with a velocity proportional to the first power of the light intensity (and dissociate *bi-molecularly*).

(a) The simplest conceivable hypothesis is that of a complex  $C_6H_6 \cdot I$ . If the following mechanism is adopted:—

then the stationary concentration of the complex becomes:—

$$[C_6H_6 \cdot I] = \frac{c_2}{c_3} [C_6H_6] \sqrt{\frac{2N_{h\nu}}{c_4}} \quad . \quad . \quad . \quad (a)$$

All the empirical rules are fulfilled, *viz.* proportionality to  $\sqrt{L}$  and  $[C_6H_6]$ , independence of  $[I_2]$ . This explanation, however, presents difficulty in the necessity of assuming that the complex  $C_6H_6 \cdot I$  absorbs visible light, which is not absorbed either by  $C_6H_6$  or by  $I$  atoms alone. Since *two* complexes  $C_6H_6 \cdot I$  can be formed at the expense of *one* molecule  $I_2$ , the molecular extinction coefficient of  $C_6H_6 \cdot I$  must be greater than half the extinction coefficient of  $I_2$  in order to account for the occurrence of the negative effect.

(b) In order to avoid the last-named difficulty, one may think of complexes involving  $I_2$ , e.g.,  $C_6H_6 \cdot I_2$ . To comply with the square root law these complexes ought either to be formed via iodine atoms, or dissociate bimolecularly:—

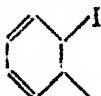

Either:

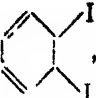

Or:

Reaction III (2) is difficult to justify. (II) is, however, not quite improbable. We may, for example, suppose that an  $I$  atom breaks

one double bond in  $C_6H_6$ , and that a radical  is formed, which is capable of reacting with a molecule of  $I_2$ .

The compound , which would then play the rôle of the "photo-

complex" can reasonably be supposed to be unstable and dissociate into  $C_6H_6$  and  $I_2$ . The stationary state, corresponding to the equation system (II) is

$$[C_6H_6 \cdot I_2] = \frac{c_2}{c_3 c_4} \sqrt{\frac{2N_{\nu}}{c_4}} [C_6H_6] \quad . \quad . \quad . \quad (b)$$

and agrees with all the observed relationships, just as in the case of (a).

It is, of course, possible for the photocomplex to be a "solvate"  $C_6H_6 \cdot I_2$ , instead of the molecule  $C_6H_6I_2$ ; but it is then difficult to understand why iodine atoms should be necessary for its formation.

In any case, since one molecular complex can be formed at the cost of one free iodine molecule, the extinction coefficients of the complex in the visible region must be greater than those of iodine itself in order to account for the negative effect.

(c) The last possibility is that of complexes involving both iodine atoms and iodine molecules, *e g.*,

The stationary state is

$$[C_6H_6I_3] = \sqrt{\frac{2N_{\nu}}{c_3}} \quad . \quad . \quad . \quad (c)$$

and the effect must be independent of  $[C_6H_6]$ . Any attempt to introduce a dependence on  $[C_6H_6]$  by assuming an equilibrium

simultaneously introduces a dependence on  $[I_2]$ , which is contrary to the experimental results.

The foregoing discussion shows that it is not easy to find a completely satisfactory explanation of the negative effect. Hypothesis (2a) involving  $C_6H_6 \cdot I$  (or corresponding complexes of iodine atoms with other solvent molecules) appears to be the more probable of the two [(2a) and (2b)] which are consistent with the relationships deduced from the experimental results.

### Summary.

Iodine solutions in  $C_6H_6$ ,  $CH_3OH$ , and  $H_2O$ , illuminated by the light from a 1500 watt carbon arc, show a reversible increase in their extinction coefficient during illumination. Exact measurements of this effect in a benzene solution show it to be proportional to the square root of light intensity, and independent of iodine concentration (for constant number of quanta absorbed). In  $I_2$  solutions in  $CCl_4/C_6H_6$ -mixtures, the effect is proportional to the concentration of benzene.

Two explanations are offered for the occurrence of this "negative" effect—one assuming a destruction of complexes (*e g.*,  $C_6H_6 \cdot I_2$ ) by light,

the other the formation of new complexes (e.g.,  $C_6H_6 \cdot I$ , or  $C_6H_6 \cdot I_2$ ) during illumination. The first appears to be the more plausible, but the second is the only one which readily accounts for the above-mentioned experimental laws.

We heartily thank Professor F. G. Donnan, F.R.S., for his hospitality and for his kind interest in this work.

## KINETICS OF THE PARA-ORTHO HYDROGEN CONVERSION ON CHARCOAL.

BY R. BURSTEIN AND P. KASHTANOW.

*Received 9th March, 1936.*

In a previous communication<sup>1</sup> it was shown that hydrogen, adsorbed at high temperature on charcoal, decreases the activity of this catalyst to the *para-ortho* hydrogen conversion. The velocity constant shows a linear fall with an increase in the amount of the activatedly adsorbed hydrogen. While, however, with an adsorption of 0.2 c.c. of hydrogen (at 500° C.) the velocity constant of conversion decreases 30-40 times at room temperature (Fig. 1), it decreases only three times (Fig. 2) at the temperature of liquid air. A further increase in the amount adsorbed at high temperature affects the rate of conversion considerably less. The poisoning curve in the case of a conversion at 300° C. is similar to that at the temperature of liquid air (Fig. 3). To explain this phenomenon it may be assumed that centres which are not active at room temperature become active at the temperature of liquid air and at 300° C.

We shall here call these "centres of the second kind," as distinguished from those which are active at room temperature, which will be termed "centres of the first kind." The existence of two kinds of active points is also demonstrated by the shape of the poisoning curves in Figs 1 and 3.

FIG. 1.—Conversion at 300° K., poisoned at 773° K., dynamic method. The ordinates are proportional to the reaction constant  $K$ , the abscissae indicate the amount of  $H_2$  adsorbed.

<sup>1</sup> Burnstein und Kashtanov, *Acta Physic. Chem., U.S.S.R.*, 1934, 7, 465; *Nature*, 1934, 133, 571.

The half-period of conversion was calculated from the first order rate expression.

Figs. 1 and 3 show the data obtained in the experiments made by the dynamic method. The gas passed from a vessel through the catalyst during the time  $t$ . The pressure of the gas in the vessel containing the charcoal increased from  $1 \times 10^{-6}$  to  $a$  (approximately 40 mm.). The value of  $K_1$ , which is proportional to the velocity constant, was calculated by the following equation—

$$K_1 = \frac{a}{t} \ln \frac{P_1 - P_\infty}{P_t - P_\infty}$$

where  $P_1$ ,  $P_t$  and  $P_\infty$  denote the *para*.  $H_2$  percentage at the time  $t = 0$ ,  $t$ , and  $t = \infty$  i.e. in equilibrium.

Bonhoeffer, Farkas and Rummel,<sup>2</sup> in measuring the con-

version of hydrogen by the dynamic method, showed that the rate of conversion as a function of the

FIG. 2.—Conversion at 90° K., adsorption at 773° K. (static method).  
Ordinates—reciprocal of half-time of the reaction

temperature is expressed by a parabolic curve. The minimum activity lies at temperature approaching room temperature, viz., at temperatures from 90° to 300° K. they observed a negative temperature coefficient, and above 300° K. a positive one.

In his further work Rummel<sup>3</sup> measured the temperature coefficient by the static method within the range 63–106° K. and found the temperature coefficient of this reaction to be nearly zero.

The data obtained by the present writers in course of their previous researches showed different values of the temperature coefficients for pure and poisoned charcoal.

To investigate this point further, we have carried out a series of experiments with pure and poisoned charcoals by the static method within the temperature range of 20–90° K., and

FIG. 3.—Conversion at 573° K., adsorption at 573° K. (dynamic method).

by the dynamic method at 90 and 300° K. The latter experiments were made at atmospheric pressure.

<sup>2</sup> Bonhoeffer, Farkas and Rummel, *Z. physik. Chemie*, 1933, **21B**, 225.

<sup>3</sup> Rummel, *Z. physik. Chemie. A.*, 1933, **167**, 221.

### Experimental.

The experimental work was carried out in the same way as previously. The charcoal (5.5 g.) after being exposed to air was outgassed for forty-eight hours at  $950^{\circ}\text{C}$ ., and during the intervals between experiments again outgassed for twelve to fifteen hours. The charcoal was then cooled to the temperature of hydrogen adsorption, and after the adsorption of a definite amount of gas (at  $500^{\circ}\text{C}$ .) cooled again to the temperature at which the conversion was conducted. The influence of the amount of hydrogen, adsorbed at high temperature, upon the rate of conversion at  $20^{\circ}\text{K}$ .,  $60^{\circ}\text{K}$ .,\*  $77.5^{\circ}\text{K}$ ., and  $90^{\circ}\text{K}$ ., was measured by the static method. In all of these experiments the same amount of hydrogen was taken for conversion; under normal conditions it was equal to 8 c.c. per gram of charcoal, and the pressure after complete adsorption did not exceed 2 mm.

To obtain a better cooling the vessel containing the catalyst was designed as shown in Fig. 4. In this vessel better cooling is obtained than in those previously used.

In the experiments conducted by the dynamic method the hydrogen was passed through the charcoal at the rate of 25 c.c. per minute. An hour after the beginning of the experiment, samples were taken for the measurement of the concentration. Measurements were made every fifteen minutes. In the experiments at room temperature and  $-80^{\circ}\text{C}$ ., the hydrogen, before reaching the vessel containing the catalyst, was passed through a charcoal-filled tube which was immersed in liquid air. In this

FIG. 4.

FIG. 5.—Conversion within the range of  $20^{\circ}$ – $90^{\circ}\text{K}$ . Abscissae —amount of  $\text{H}_2$  adsorbed in c.c./g. (static method).

tube a mixture of 47 per cent. of *para* hydrogen was obtained.

The experiments conducted by the static method showed that the velocity constant of the *ortho-para*-conversion increased with temperature, the activity of the centres, both of the first and the second kind, increasing.

\* The temperature of  $60^{\circ}\text{K}$ . was reached by pumping out pure liquid oxygen to 5 mm.

As seen from Table I. (Fig. 5), the activity of the centres of the first and second kinds are equally influenced by temperature.

Thus, *e.g.*, within the range of 60-77.5° K., the velocity constant on pure charcoal, *i.e.*, when centres of the first kind are present, increases about twice; in the case of poisoned charcoal (0.2 c.c. H./gr.), the conversion takes place only on centres of the second kind and the constant also increases twice.

TABLE I.

Temperature °K.	Hydrogen Absorbed at 500° C. in c.c./g.	<i>t</i> in Seconds	<i>K</i> ( $\times 10^{-4}$ ).
20.4	0.0	2000	1.16
	0.0	2200	1.36
	0.23	2500	1.21
	2.51	5700	0.53
60	0.0	495	6.1
	0.206	1080	2.8
77.5	0.0	250	11.8
	0.23	520	5.78
	2.51	1470	2.06
90.0	0.0	180	10.8

The apparent energy of activation of this reaction in the range of 60-90° K. is about 350 calories for the active points of both the first and second kind.

In the experiments at 20° K. (Fig. 5) only centres of the second kind are observed. This fact may be possibly explained by a condensation of hydrogen at the most active spots of the first kind, the latter thus ceasing to take part in the conversion.

The results obtained by the present writers differ from those of Rummel, who has found the temperature coefficient of this reaction to be almost zero, while in the above experiments a positive, though small, temperature coefficient was observed both for the pure and for the poisoned charcoal (Fig. 6).

The experiments conducted by the dynamic method within the range of 90-573° K. have shown that the rate constant of this reaction on thoroughly degassed charcoal increases with temperature. Throughout this whole temperature range a positive temperature coefficient is observed.

On the other hand, in the case of a poisoned charcoal within the temperature range of 90-300° K., the *para-ortho*-conversion has a negative temperature coefficient, and within the range of 300-573° K., a positive one.

Fig. 7 and Table II.

give data expressing the relation between the rate constant and the temperature for pure (I.) and poisoned (II.) charcoal.

As it is very difficult to investigate the conversion at atmospheric pres-

FIG. 6.—Increase of constant with temperature (static method). I. Pure charcoal. II. Poisoned charcoal.

sure and at 573° K., because the reaction is self-poisoned by the activated adsorption, the conversion was observed at 40 mm. Hg. The data obtained show that the velocity constant increases  $\pm 1.5$ -fold in the temperature range 293-573° K. on pure charcoal, and 5-fold on the poisoned charcoal. The

values in Table II. were calculated from these data.

With pure charcoal the apparent energy of activation calculated from experiments conducted by the static method is of the same order as that calculated from experiments made by the dynamic method. In the latter case the energy of activation throughout the whole temperature range (90-573° K.) varies from 130 to 409 calories.

We can obtain a better agreement between the values of the activation energy for active points of the first kind, calculated from the experiments using the dynamic and static method, if we subtract from the reaction constant of pure charcoal the reaction constant corresponding to the points of second kind. The energy of activation calculated in that way varies throughout the temperature range 90-573° K. from 460 to 210, whereas the static method gives 350 cal. in the range 60-90° K.

For the centres of second kind we find from the dynamic experiments—1300 cal. in the range 193-293° K., as against 350 cal. given by the static method of low temperature.

Generally speaking, the rate constant calculated from the results obtained by the static method may differ considerably from that obtained by the dynamic method. All the experiments made by the static method refer to a definite concentration of gas in

the surface layer, while those conducted by the dynamic method refer to a definite pressure.

The relation between the two values obtained for energy of activation can be explained as follows: The adsorption of hydrogen at room temperature is already sufficient to cover the centres of the first kind, so

Fig. 7. Dependence of constant on temperature (dynamic method). I. Pure charcoal. II. Poisoned charcoal.

TABLE II

Temperature (°K.)	Amount of Hydrogen Adsorbed at 500° C. in cc. g.	K.
Pure charcoal.		
90	0.0	1.85
193	0.0	2.94
293	0.0	3.30
573	0.0	(calcul.) 4.62
Poisoned charcoal.		
90	0.45	1.23
193	0.41	0.51
293	0.41	0.16
573	0.37	(calcul.) 0.81

that the increase of adsorption with a fall of temperature does not affect the rate of the reaction. In this case the results obtained by the dynamic method become comparable with those obtained by the static method. The course of curve I. (Fig. 7) shows that throughout the whole temperature range studied the mechanism of the conversion is the same.

To explain the results obtained with active points of the second kind we have to suppose that, in this case, the concentration of hydrogen in the reaction space changes with temperature. As the heat of activation is much smaller than the heat of adsorption this accounts for the negative temperature coefficient. The data obtained by the present writers for poisoned charcoal are in agreement with those of Bonhoeffer.

The heat of adsorption being 1600 cal. and the apparent heat of activation — 1300 cal., we can calculate the true energy of activation which is 300 cal. This result is in good agreement with the data obtained by the static method, and with the value of the energy of activation on points of the first kind.

These considerations are correct if the reaction on the points of second kind is of the first order.

It is yet not quite clear whether the positive coefficient observed in the temperature range 300-573° may be connected with a new mechanism, as was supposed in similar cases by Bonhoeffer.

### Summary.

On the surface of charcoal there are active centres of two kinds.

Experiments conducted by the static method have shown that the *ortho-para* hydrogen conversion on charcoal within the temperature range of 20-90° K. has a positive temperature coefficient. With a rise of temperature the activity of the centres of both the first and the second kind increases.

At 20° K. the centres of the first kind cease to be active. The apparent energy of activation of the *ortho-para*-conversion within the range of 20-90° K. is 350 calories.

Experiments carried out by the dynamic method with pure charcoal have shown that within the temperature range of 90-573° K. a positive temperature coefficient is observed. In similar experiments with poisoned charcoal within the range of 90-300° K. a negative temperature coefficient is observed, while within the range of 300-573° K., the coefficient is positive.

The study of the kinetics of the *para-ortho* hydrogen conversion on charcoal is being continued by the authors.

We are indebted to Professor A. N. Frumkin for the interest he has shown to this work, and to Professor L. V. Shubnikov who has afforded us the possibility of conducting experiments with liquid hydrogen at his laboratory in the Physico-Technical Institute.

# THE HOMOGENEOUS CATALYTIC OXIDATION OF BENZENE.

BY R. H. GRIFFITH AND S. G. HILL.

*Received 12th March, 1936.*

The oxidation of benzene in silica or porcelain bulbs was found by Fort and Hinshelwood<sup>1</sup> to be a homogeneous reaction in which relatively short chains played a part, and where the change was favoured by a high concentration of hydrocarbon. Newitt and Burgoyne<sup>2</sup> also showed that the non-catalytic oxidation of benzene under pressures of about 50 atm. at 280° and upwards was retarded by increased surface. In view of the fact that ethyl nitrate is known to have a marked effect on the spontaneous ignition temperature of aromatic hydrocarbons, and is of the type recognised by Ubbelohde and Egerton as pro-knocks, it appeared to be of interest to study the slow combustion of benzene in the presence of this catalyst.

The results which are now described are to be regarded as a survey of the conditions which exist in the presence of a vapour-phase catalyst.

## Experimental Method.

The apparatus consisted of a Pyrex glass bulb of about 500 c.c. capacity, as shown in Fig. 1, heated in an electric

furnace and connected to a source of purified oxygen and to an evacuation system and manometer. A small bulb C, of about 1 c.c. capacity, was used for admission of liquid benzene (analytical reagent quality) containing the desired amount of ethyl nitrate. The capillary connections and the manometer tube were heated to about 60°-65° by fine resistance wires up to the mercury level, in order to prevent condensation of liquid benzene. The change in total volume due to alteration in the manometer level was so small that it was neglected, and the system was regarded as one of constant volume. The course of the reaction was followed by determining the increase in pressure, and by subsequent analysis of the gaseous products. Typical curves are shown in Fig. 6, where it is clear that no induction

FIG. 1.

<sup>1</sup> *Proc. Roy. Soc., A*, 1930, 127, 218.

<sup>2</sup> *Ibid.*, 1936, 153, 448.

period was observed in any case. Newitt and Burgoyne<sup>2</sup> also found that no induction period appeared in the slow oxidation of benzene under pressure.

FIG. 2.

Initial pressure, 620 mm.

Temperature, 433°.

FIG. 3.

Ratio  $C_6H_6 : O_2 = 1 : 1$ .

Temperature, 433°.

$EtNO_3 = 0.1$  per cent. of initial pressure.

A standardised procedure was adopted in order to clean the bulb at the end of each experiment, so that the surface was in a similar condition before a new determination was carried out. The bulb was exhausted to

$10^{-4}$  cm. at  $450^\circ$  or at any higher temperature which was investigated. The benzene in bulb C was then admitted to the reaction vessel, and the desired amount of oxygen, prepared from potassium permanganate and stored over 50 per cent. calcium chloride solution, was allowed to enter.

### Results Obtained.

(a) **Ratio of Benzene to Oxygen.**—Experiments at  $433^\circ$  with an initial total pressure of 620 mm. and 0.62 mm. of ethyl nitrate (0.1 per cent. of initial pressure) were carried out to determine the effect of changes in the relative concentrations of benzene and oxygen. These are summarised in Fig. 2, where the time of half-change is seen to depend directly on the ratio

(b) **Pressure.**—

In Fig. 3, the influence of pressure is shown for an equimolecular mixture of benzene and oxygen at  $433^\circ$ , with ethyl nitrate equal to 0.1 per cent. of the total pressure. It will be seen that the reaction is approximately one of the third order, but probably of an even higher order at low pressures.

(c) **Temperature.**—The variation in the time of half-change with temperature is shown in Fig. 5, for a mixture of  $C_6H_6 + 2O_2$ , and ethyl nitrate 0.1 per cent. of the total initial pressure of 620 mm.

FIG. 4.

Temperature,  $435^\circ$ .  
Pressure, 620 mm. initial.  
Ratio  $C_6H_6 : O_2 = 1 : 2$ .

(d) **Concentration of Ethyl Nitrate.**—It was found that with a  $C_6H_6-2O_2$  mixture at  $433^\circ$ , with initial pressure 620 mm., the time of half-change varied inversely as the concentration of ethyl nitrate. This is shown in Fig. 4, from which it was to be expected that the reaction with 0.35 per cent. or more of ethyl nitrate would be so rapid that the mixture would explode. This was found to be the case with both 0.35 and 0.4 per cent. concentrations.

(e) **Effect of Surface.**—Comparative experiments with the empty bulb and with a similar bulb containing Pyrex glass tubes which gave a

surface approximately ten times as great were done at  $430^\circ$  and  $435^\circ$  with benzene : oxygen = 1 : 2 and ethyl nitrate 0.1 per cent. of an initial total pressure of 620 mm. It will be seen from Fig. 6 that considerable retardation occurs which is slightly more pronounced at the lower temperature. It was also observed that slight decomposition of benzene which contained no ethyl nitrate took place in the packed bulb although it was not detected in the empty bulb.

(f) **Effect of Tetra-Ethyl Lead.**—The effect of simultaneous presence

of ethyl nitrate and tetra-ethyl lead is illustrated by Fig. 7, where it is clear that the oxidation is greatly suppressed by the addition of the knock inhibitor.

FIG. 5.

$C_6H_6 : O_2 = 1 : 2$ .  
 $EtNO_2 = 0.1$  per cent. of initial pressure.  
 Initial pressure, 620 mm.

### Composition of Reaction Products.

It was observed that although the increase in pressure reached a maximum and remained at that point for some time, a gradual decrease in pressure then set in and progressed slowly during very long times. This is probably due to polymerisation reactions which lead to the formation of diphenyl or diphenyl oxide, and a crystalline deposit was, in fact, observed on the walls of the bulb when cold. By washing the vessel with alcohol and diluting the washings with water, a solid was extracted and after recrystallisation it melted at  $71^\circ$ . The residue had the characteristic odour of diphenyl oxide, but there was no indication that phenol or diphenylene oxide were also present.

Gas samples were withdrawn from the hot bulb by way of a U-tube cooled in solid carbon dioxide mixed with acetone; this

retained any unchanged benzene or condensable products. The composition of the permanent gas is shown in Tables I. and II. for a variety of conditions. The varying content of nitrogen is accounted for by the small volume of air which was unavoidably present when bulb C was not completely filled with benzene.

### Discussion.

The general characteristics of the catalysed reaction at 430°-480° are very similar to those of the uncatalysed reaction at 500°-530°. The catalyst acts as a chain initiator and its effect is counteracted by glass surface or by lead tetra-ethyl. The chains appear to be relatively short, but direct comparison with the uncatalysed reaction is not possible. The reaction approximates to one of third order, but the ethyl nitrate concentration affects the rate directly, so that the true order is one

lower. The fact that increase in the oxygen concentration leads to a decrease in reaction velocity agrees with the data of Fort and Hinshelwood on the uncatalysed reaction, and with the conclusions of Ubbelohde.<sup>3</sup> The solid reaction products which have been isolated are similar to those

detected by Mead and Burk<sup>4</sup> in the thermal decomposition of benzene.

The composition of the gaseous products shows several regular gradations; increase of oxygen leads to a higher  $\text{CO}_2/\text{CO}$  ratio, while a rise in the reaction temperature has the opposite effect. The presence of lead tetra-ethyl, or of additional glass packing in the bulb, gives a high residual concentration of oxygen. When the concentration of ethyl nitrate is increased, the ratio of  $\text{CO}_2/\text{CO}$  decreases slowly until explosion occurs, when a gas mixture of an entirely different type is formed, similar to that observed by Bone and Hill<sup>5</sup> for the explosion of ethane. The influence of total

The production of acetylene was observed in several instances, particularly with higher concentrations of ethyl nitrate.

The fact that phenol was not detected under these conditions, although it was formed in large yields in the experiments of Newitt and Burgoyne, is probably chiefly due to the higher temperatures employed in the present investigation, but may also be caused by the influence of the catalyst on the combustion of any phenol which is formed.

### The Function of the Catalyst.

Ethyl nitrate conforms to the type of pro-knock anticipated by Egerton and Ubbelohde,<sup>6</sup> but certain observations on its thermal decomposition do not supply evidence for the suggested mechanism. It was found that ethyl nitrate decomposed in the glass bulb at  $435^\circ$  giving, for example, a pressure increase of 106 mm. in 220 minutes from an initial

<sup>6</sup> *Nature*, 1935, 135, 67.

pressure of 269 mm. The reaction products were withdrawn by way of a tube cooled in solid carbon dioxide, and contained

## REVIEW OF BOOK.

**Lehrbuch der Physikalischen Chemie.** Vol. V, 2nd Section. By K. JELLINEK. (Stuttgart, Ferdinand Enke. Pp. 289-576 + 185 figs. 27 RM.)

This continuation of the monumental textbook of Dr. Jellinek treats mainly with the properties of the atom. It is the most physical of the sections that have appeared so far, and has probably been introduced into the textbook of physical chemistry because it will form the basis of the next section on molecular structure. Among the topics dealt with are mass spectroscopy, the scattering of  $\alpha$ -particles, atomic spectra, and the Bohr and Sommerfeld theories, X-rays and their reflection by crystals, the theory of spectra including the Pauli principle, the Periodic Table, radioactivity and isotopes, inelastic collisions between nuclei and various projectiles and artificial radioactivity.

The present section maintains the good features of the earlier volumes and is very clearly written with full experimental and mathematical details throughout. It is an admirable work of reference if only for the facts it contains, but it is more than that, for the facts have been welded into a continuous story of very great interest. The section on the nucleus is especially valuable, since the author surveys the whole field in short compass, up to the present day.

The work is excellently printed, and to aid the non-mathematical reader the mathematical and more technical details are presented in small type.

W. E. G.

# THE SURFACE ANALYSIS OF PARTICLES OF CERTAIN WHEAT FLOURS.

BY IAN KEMP.

*Communicated by* ERIC K. RIDEAL.

*Received 18th February, 1936.*

Wheat flour consists essentially of starch, proteins (of which gliadin and glutenin form the major part) lipoids and electrolytes. A suspension of flour will therefore consist of starch particles upon whose surfaces may be adsorbed proteins or lipoids. It is of importance in the colloid chemistry of flour to form some estimate of the *fractions* of the surfaces of the particles of starch which are covered with protein and with lipid.

For the estimation of the distribution of capillary active substances over the surface of a composite colloidal particle, it is necessary to select some additive surface property, and one of the more convenient methods is the measurement of the surface charge density on the particle by cataphoresis.

Thus, in the case of flour, if  $\sigma_p$ ,  $\sigma_l$ ,  $\sigma_s$  be the surface charge densities of the protein, lipid, and starch surfaces respectively, and  $f_p$ ,  $f_l$  be the fractions of the surface of the starch particle covered with protein and with lipid respectively, then if we assume that the surface charge densities are additive, the resultant surface charge density of the flour particle is

$$\sigma = f_p \sigma_p + f_l \sigma_l + \sigma_s (1 - f_p - f_l) \quad (1)$$

In practice the cataphoretic mobility of particle is proportional to its surface charge density, the relation having been shown previously (Kemp)<sup>1</sup> to be satisfactorily expressed by the equation of Henry.<sup>2</sup>

$$\mu = \frac{\sigma}{\eta} \cdot \frac{ka}{1 + ka} f(ka) \quad (2)$$

where  $\mu$  denotes the cataphoretic mobility,  $\sigma$  the surface charge density,  $\eta$  the coefficient of viscosity of the solution,  $a$  the radius of the particle,  $k$  is proportional to the square root of the ionic strength, and  $f(ka)$  is a function of  $ka$ . According to this equation, the variation in mobility with particle size is negligible for the purpose of the present experiments when  $ka$  is greater than 100. Thus equation (1) can be written

$$(\mu - \mu_s) = (\mu_p - \mu_s) f_p + (\mu_l - \mu_s) f_l \quad (3)$$

where  $\mu$ ,  $\mu_p$ ,  $\mu_l$ ,  $\mu_s$  are the mobilities of particles of flour, protein lipid and starch respectively, the particles being of similar size and the  $ka$  value not being much less than 100. The values of these mobilities are determined by the ionic environment, and hence by measuring the

<sup>1</sup> Kemp, *Trans. Faraday Soc.*, 1935, **31**, 1347.

<sup>2</sup> Henry, *Proc. Roy. Soc.*, 1931, **133A**, 106.

mobilities of the four types of particle in two different ionic environments, the values of  $f_p$  and  $f_i$  can be calculated from the equations :

$$(\mu' - \mu'_s) = (\mu'_p - \mu'_s) f_p + (\mu'_i - \mu'_s) f_i \quad (4)$$

$$(\mu'' - \mu''_s) = (\mu''_p - \mu''_s) f_p + (\mu''_i - \mu''_s) f_i \quad (5)$$

for the mobilities in the two cases.

It was therefore necessary to investigate the cataphoretic behaviour of proteins, lipoids and starch of flour, and finally of flour itself in suitable solutions. In practice the particles employed were never much less than  $1\mu$  in size and the ionic strength was 0.001, so that  $ka$  was about 100, and the effect of small variations in particle size upon the mobility could be neglected.

By such methods it was found possible to make some estimate of the amounts of proteins and of lipid on the surfaces of the starch particles in suspensions of flour.

**1. Experimental.**—Measurements of cataphoretic mobility were made with a microcataphoresis apparatus of the Mattson type. Measurements of hydrogen ion activity were made with the quinhydrone and glass electrodes.

**2. Glutenin.**—Samples of this protein from two sources were investigated, one having been prepared in the laboratory of the Research

Association of British Flour Millers, and the other in the United States of America. The variation of mobility with ionic environment was determined for silica particles covered with glutenin and no appreciable difference between the two samples was noted. The detailed results are given graphically as Fig. 1.

The data regarding the isoelectric point are collected in Table I. The effect of excess anionic adsorption is clearly seen, and the isoelectric reaction at "infinite dilution" may be taken as  $p_H$  4.90.

**3. Gliadin.**—In a previous publication (Kemp and Rideal) \* the isoelectric point of gliadin was shown to be at  $p_H$  5.10 in very dilute solutions. The sample of gliadin used had been allowed to stand in 70 per cent. alcoholic solution for some days before measurements were made.

In order to investigate the possibility of alcohol-denaturation having occurred, the isoelectric  $p_H$  of gliadin which had been dissolved in dilute acetic acid was determined. The sample of gliadin, which was prepared by the Research Association of British Flour Millers, was adsorbed on silica particles for the mobility measurements. The results are shown in Fig. 1, and it will be noted that the isoelectric reaction is  $p_H$  6.60  $\pm$  0.05 in solutions of ionic strength 0.001 (curve 5). This value is in agreement with results of other workers. It is clear that, on standing in alcoholic solution, denaturation of the gliadin occurs, with the disappearance of basic groups. This was further corroborated by a measurement of the isoelectric reaction of a sample which had been allowed to stand in 70 per cent. alcohol for four days, when the isoelectric  $p_H$  had fallen to 5.92  $\pm$  0.05. The results are expressed as curve 4 of Fig. 1.

**4. Natural Protein Mixtures.**—The natural protein mixtures were isolated from flours by extracting the lipoids with petroleum ether, and removing the starch by kneading in a stream of water.

TABLE I.

× Phosphate buffers.  
○ Acetate buffers.

\* Kemp and Rideal, *Proc. Roy. Soc.*, 1934, 147A, 1.

The cataphoretic behaviour of the protein mixture from a sample of Manitoba flour is shown graphically in Fig. 2. The isoelectric reaction is at  $p_H$   $5.63 \pm 0.05$  in solutions of ionic strength  $0.02$  and  $p_H$   $6.50 \pm 0.05$  in an ionic strength of  $0.001$ .

FIG. 4.—The lipids of flour.

Curve 1. Lipids from Manitoba flour in ionic strength  $0.02$ . ● Acetate buffer.  
 " 2. " " " " " " " " 0.001. ○ Phosphate buffer.  
 " 3. " " English " " " " " " 0.001.

In Fig. 2 is also shown the effect of alcohol denaturation on the isoelectric  $p_H$ . Thus, treatment with 70 per cent. alcohol for 40 hours reduces the isoelectric  $p_H$  to  $6.15 \pm 0.05$  (curve 2, Fig. 2).

FIG. 5.—Gluten from Manitoba flour.

Curves 1, 4. Ionic strength  $0.02$ . ● Acetate buffers.  
 " 2, 3. " " " " 0.001. × Phosphate buffers.

From the results of sections 2 and 3, it would seem that the protein mixture of Manitoba Flour has a larger surface fraction of gliadin than of glutenin. In the case of the natural protein mixture from English flour, the results are given in Fig. 3, from which it will be seen that the mixed protein is isoelectric at  $p_H$   $6.16 \pm 0.04$ . It would seem from these

results that the surface gliadin-glutenin ratio is greater in Manitoba than in English flour.

It will be seen from Figs. 1, 2, and 3, that the electrophoretic behaviour of the protein mixture obtained by kneading ether-extracted flour is not

FIG. 6.—Gluten from English flour in solutions of ionic strength 0.001.

Curve 1. Untreated. × Phosphate buffers.  
 Curve 2. Heated to 90° C. for 6 hours. ● Acetate buffers.

completely explained by the behaviour of the two main constituent proteins, gliadin and glutenin. The difference may be due to the persistence of a lecithin protein complex after ethereal extraction.

FIG. 7.—Wheat starch in solutions of ionic strength 0.001.

● Acetate buffer.  
 ○ Phosphate buffer.

5. The \* Lipoids of Flour.—The lipoids of flour were extracted with petroleum ether, and acetone was added after partial removal of the petroleum ether. The acetone solution was mixed with water to give a dispersion of lipoids, and the solvents were removed by aeration. The results are given in Fig. 4.

\* The term "lipoids" denotes here all petroleum-ether soluble substances.

**6. The Glutens from Flour.**—The cataphoretic behaviour of gluten obtained by kneading Manitoba Flour is expressed in Fig. 5. The isoelectric reaction of the gluten is  $p_H$   $5.72 \pm 0.07$  in acetate buffers, and  $p_H$   $6.12 \pm 0.05$  in phosphate buffers, of ionic strength 0.02, and  $p_H$   $6.30 \pm 0.07$  in phosphate buffers of ionic strength 0.001.

The application of the additive rule to these results, in conjunction with those of sections 4 and 5, indicates that the mean value of the surface fraction of natural mixed proteins is 0.9. In the case of English flour (Fig. 6), the surface fraction of proteins also varies about a mean figure of 0.9. The effect of heat denaturation upon the cataphoretic behaviour of gluten from English flour was investigated, the results being given in Fig. 6. The isoelectric point is changed from  $p_H$   $6.44 \pm 0.05$  to  $p_H$   $5.92 \pm 0.05$  by heating to  $90^\circ$  C. for 6 hours, and it is inferred that during the process of baking, basic groups of the protein disappear.

**7. Starch.**—The cataphoretic behaviour of wheat starch is shown in Fig. 7.

**8. Flours.**—The mean mobilities of the particles of Manitoba and English flours were measured in acetate buffers of ionic strength 0.001 (see Table II.). If we denote by  $f_G$  the fraction of gluten on the surface of the "average" flour particle, then assuming an additive law, we have

TABLE II.

Flour.	$p_H$ .	Mobility.
Manitoba .	3.90	+ 1.20
	4.80	+ 0.60
English .	3.86	+ 0.96
	3.92	+ 0.92

$$\mu_F = f_G \mu_G + (1 - f_G) \mu_S$$

where  $\mu_F$ ,  $\mu_G$  and  $\mu_S$  denote the mobilities of particles of flour, of gluten, and of starch respectively. From the results of sections 6 and 7, the fractions of gluten on the surface of particles of Manitoba flour obtained are 0.78 at  $p_H$  3.90 and 0.79 at  $p_H$  4.80. In the case of English flour, no results were available for the mobility of gluten particles in acetate solutions of ionic strength 0.001. However, it was possible to obtain an approximate value of the mobility of the gluten from English flour in these solutions by combining the results of sections 4, 5 and 6 with the conclusion of section 6 that the surface fraction of mixed proteins in the gluten particle from English flour is approximately 0.9. Thus the mobility of particles of English gluten could be obtained from the mobilities of particles of the natural mixed proteins (section 4) and of the lipoids (section 5). This method gave an approximate value of 0.8 at  $p_H$  3.9 for the surface fraction of the particle of English flour covered with gluten.

There is apparently little difference between the surface composition of the particles of English and Manitoba flours, the fraction of the surface covered with gluten being in each case about 0.8.

### Summary.

1. A method for the surface analysis of colloidal particles is described.
2. The cataphoretic behaviour of the following colloidal constituents of wheat flours has been studied :—

- (a) Glutenin. The effect of salt concentration on the isoelectric reaction is discussed.
- (b) Gliadin. Alcohol-denaturation is shown to eliminate basic groups, shifting the isoelectric point to the acid side.
- (c) Natural protein mixtures from Manitoba and English flours.
- (d) Lipoids from the two flours.
- (e) Glutens from the two flours. The effect of baking is to shift the isoelectric point to the acid side, showing that basic groups are removed.
- (f) Wheat starch.

3. The distribution of proteins and lipoids over the surface of particles of the flours is discussed. The results indicate that for Manitoba and English flours the fraction of the particle surface covered by gluten is about 0.8.

The author desires to thank Professor E. K. Rideal, F.R.S., for his encouragement and assistance, and the Research Association of British Flour Millers for financial assistance in this work and for permission to publish the results. He is also indebted to Dr. E. A. Fisher for helpful discussions.

## SUBSTITUTION AND INVERSION OF CONFIGURATION.

By E. BERGMANN, M. POLANYI AND A. L. SZABO.

*Received 25th February, 1936.*

In a previous paper<sup>1</sup> the authors communicated experiments on the racemisation of optically active methyl butyl and methyl propyl iodomethane by iodine ions, and connected their results with the known data on substitution of the analogous chlorides by iodine ions. Before presenting our further experiments<sup>2</sup> we wish to make clear the previous development leading up to our own work.

Walden inversion was first connected with the spatial mechanism of the substitution, by A. Werner.<sup>3</sup> His ideas, which have been further developed by A. Meisenheimer<sup>4</sup> may be demonstrated for the case of the alkaline hydrolysis of methylchloride. This is supposed to occur in two steps, the first of which is the addition of one molecule of KOH to the methyl chloride

linking the potassium atom to the chlorine atom. The formation of this compound involves a distortion of the carbon tetrahedron reinforcing the positive character of the central carbon atom, and enabling a second molecule of KOH to combine through the oxygen atom with the methyl chloride molecule

<sup>1</sup> *Z. physik. Chem. (B)*, 1933, **20**, 161.

<sup>2</sup> For a preceding publication of these results see the thesis of one of the authors; A. Szabo, *Diss. Berlin*, 1933.

<sup>3</sup> *Lehrbuch der Stereochemie*, Jena, 1904, pp. 14 and 15.

<sup>4</sup> *Liebig's Ann.*, 1927, **456**, 126.

From this complex, methyl alcohol is formed either with the KOH molecule to the left or with that to the right, inversion occurring in the former, not in the latter case.

Although the theory of Werner and Meisenheimer is certainly incorrect in detail and does not allow one to predict the course of any particular reaction, it gives an important lead by suggesting a spatially directed mechanism of substitution.

Br. Holmberg<sup>4a</sup> (writing a year before Meisenheimer's paper appeared) attempted another detailed picture of spatially directed substitution; we present it in the form given by Wagner-Jauregg.<sup>5</sup> When colliding with a molecule BY, the compound  $abdCX$  is supposed to take up the alternative series of arrangements (1) or (2)

The first process leads to inversion of configuration, while in the latter case the original configuration is retained. Whether the former or the latter prevails is supposed to depend on the "reaction distance"  $Y-B$ . The predictions based on this theory have, as Wagner-Jauregg<sup>5</sup> remarks, in general not been borne out by experiments.

To the alkali chlorides acting on organic halides Holmberg attributes a large "reaction distance"  $Y-B$  between the kation and anion, or alternatively suggests that the anion might act alone with a large "reaction distance"  $E-A$ , representing the distance between the anion  $A$  and its negative charge  $E$ . This description of the substitution (which fails to convey any meaning to us), is used by Holmberg to account for the tendency discovered by him for substitution by negative ions to produce inversion of configuration. Holmberg does not claim that substitution by negative ions necessarily leads to inversion of configuration. This is apparent in the following formulation which he gives for his explanation of the racemising effect of halogen ions on halogeno-succinic acids:

where  $\phi$  is the fraction of substitution reactions leading to inversion and  $(1 - \phi)$  the fraction reacting *without* configurational change.

Holmberg's general idea, that racemisation of this type is due to atomic interchange reactions, has since been confirmed. The evidence given by Holmberg, however, was questioned by Wagner-Jauregg,<sup>6</sup> who suggested that the racemisation of bromo-succinic acid and similar compounds is due to enolisation.

The theoretical situation in 1931 seems to be correctly characterised

<sup>4a</sup> *Ber.*, 1926, **59**, 126.

<sup>5</sup> Freudenberg's *Stereochemie*, Vienna, 1933, p. 908.

<sup>6</sup> *Monatshefte der Chemie*, 1929, **53-54**, 791.

by Hueckel.<sup>7</sup> "Hitherto none of the speculations on the course of a substitution at an asymmetric carbon atom is based on experimental evidence. None of these speculations give a definite lead to experiments to set an aim to further investigation."

In a paper by N. Meer and one of the authors<sup>8</sup> it was pointed out that, when a substituent of the negative type is exchanged for a negative ion, the driving force of the reaction must lie in the interaction of the negative ion with the carbon atom to which it becomes attached in the course of the reaction; the effect of the positive ion is restricted to a "salt effect." It was further pointed out that the negative ion will necessarily approach the carbon atom from the side opposite to the group to be substituted, since the electrostatic forces of the dipole attacked by the ion will cause this to be a position of minimum energy. In consequence it was claimed that substitution by negative ions is necessarily connected with configurational inversion.

As evidence for the correctness of these views it has been pointed out that substitution by negative ions is accompanied by steric hindrance when voluminous substituents are attached to the carbon atom at which the substitution takes place.

Further strong evidence in favour of the theory of Meer and Polanyi were given by the present authors.<sup>1,2</sup> The kinetic analysis by Olson and Long<sup>3</sup> of the substitution of optically active halogen succinic acids by halide ions offers an even more conclusive proof of this theory. A direct demonstration of its correctness has recently been given by Hughes, Juliusburger, Masterman, Topley and Weiss,<sup>10</sup> who showed that atomic interchange between radioactive iodine ions and optically active alkyl iodides is accompanied by inversion of symmetry.

### General Results.

The following two conclusions drawn from the theory of substitution have been tested or partly tested. 1. The racemisation of an optically active halide by the corresponding halogen ion should follow the laws which are known to obtain in substitutions by halogen ions, *i.e.*, the velocity constant should be expressed by the Arrhenius equation containing a temperature independent factor of about  $10^{10}$ . 2. The magnitude of these constants should quantitatively fit into a pattern which includes the analogous substitution reactions (Table I.). In

TABLE I.

Organic Halide.	Inorganic Ion.			
	F <sup>-</sup> .	Cl <sup>-</sup> .	Br <sup>-</sup> .	I <sup>-</sup> .
Fluoride . . . .	Rac.	Subst.	Subst.	Subst.
Chloride . . . .	Subst.	Rac.	Subst.	Subst.

Iodide . . . .	Subst.	Subst.	Subst.	Rac.

any vertical or horizontal column of this pattern the velocity constants should show a monotonous sequence, so that it should be possible to calculate the rates of racemisation by interpolating or extrapolating from

<sup>7</sup> *Theoretische Grundlagen der organischen Chemie*, Leipzig, 1931, p. 288.

<sup>8</sup> N. Meer and M. Polanyi, *Z. physik. Chem.*, 1932, 19B, 164.

<sup>9</sup> *J. Amer. Chem. Soc.*, 1934, 56, 1294.

<sup>10</sup> *J. Chem. Soc.*, 1935, 1525.

the rates of substitution. Monotonous sequence should also be found along the diagonals of the table, and along lines parallel to these.

FIG. 1.—Velocity constants of the racemisation of methylpropyl iodomethane by NaI.

The main difficulty in following the sequences set out in the above table for any single compound is that the range of velocities is too wide. In consequence one has to change over from one radical to another and to calculate the missing data by relating the values which could be determined for both cases. In view of the uncertainties involved in the use of compounds where enolisation is possible we chose for our investigation pure secondary alkyl halides, namely, methyl-butyl, methyl-propyl, and methylphenyl halogenomethanes.

The results obtained for the reaction between iodomethane and iodine ions are summarised in Figs. 1 and 2. The curves represent the bi-molecular velocity constants

$$k_2 = \frac{1}{2 \cdot c \cdot t} \cdot \log \frac{\alpha_0}{\alpha_t}$$

where  $\alpha$  is the observed rotation,  $t$  the time in minutes and  $c$  the concentration of the inorganic halide.

The factor  $\frac{1}{2}$  is due to the substitution of each molecule wiping out the optical activity of two active molecules.

The Arrhenius equations representing  $k_2$  change slightly with concentration; for 0.1  $N$  concentration of  $I^-$  we found

$$\log k_2 = \log 10^{10.7} - \frac{17000}{2.3 RT}$$

for methylbutyl iodo-methane, and

$$\log k_2 = \log 10^{11.0} - \frac{17400}{2.3 RT}$$

for methylpropyl iodo-methane.

While the activation energy does not show a definite trend with concentration, the values for the collision number decrease with increas-

FIG. 2.—Velocity constants of the racemisation of methylbutyl iodomethane by NaI.

ing concentration (as shown by the curvature) owing to the decrease of activity of the iodine ions with increasing concentration. The decrease is from  $10^{10.9}$  to  $10^{10.6}$  for methylbutyl- and from  $10^{11.1}$  to  $10^{10.9}$  for methylpropyl iodomethane. These values are in satisfactory agreement with the collision numbers found in other reactions involving substitutions by negative ions.<sup>11</sup>

Our further results are listed in Table II. From the data for the first three reactions, in conjunction with the value of the velocity constant of

TABLE II.—SUBSTITUTION REACTIONS IN ANHYDROUS ACETONE.

	Temp. °C.	$k_2$	$c_{\text{inorg.}}$
1. Methylbutyl-bromomethane + NaJ	30	$1.3 \times 10^{-3}$	0.3037
2. Methylbutyl-chloromethane + NaJ	50	$7.4 \times 10^{-3}$	0.3005

the corresponding racemisation, a sequence is obtained which corresponds to the last column of Table I. This sequence is presented for the common temperature of 50° C. in Table III. In computing these data, a temperature coefficient of 2.4 per 10° (as observed for reaction 2) was assumed for reaction 3. We also made the obviously justifiable assumption, that the value for methylbutyl fluoromethane is the same as that measured for methylpropyl fluoromethane.

The reaction velocities form a monotonous series, thus confirming the expectation expressed above. There is an increase in the sequence  $F \rightarrow Cl \rightarrow Br \rightarrow I$ , as usually found in analogous cases. An extrapolation based on the first three figures of the sequence yields a value for the racemisation of the iodide, which is in satisfactory agreement with the measured one.

A second shorter sequence included in the data given above is that of the reactions of phenylmethyl chloromethane with chloride and iodide ions respectively. The considerable increase of reaction rate on passing from  $Cl^-$  ( $k_2 = 5.7 \times 10^{-3}$ ) to  $I^-$  ( $k_2 = 1.0 \times 10^{-3}$ ) is analogous to the increase referred to above in the series of organic halides.

We have attempted and failed to determine the racemisation velocity of methylbutyl chloromethane by chloride ions; the optically active compound showed no decrease in rotation when exposed to the influence of 0.036 mol. LiCl at 50° C. for fourteen days. This result can be accounted for by the following rough calculation. Assuming that the ratio of velocities for the two pairs of reactions (a) phenylmethyl-chloromethane +  $I^-$  ( $1.0 \times 10^{-3}$ ) and phenylmethyl chloromethane +  $Cl^-$  ( $5.7 \times 10^{-3}$ ), and (b) methylbutyl chloromethane +  $I^-$  ( $1.2 \times 10^{-3}$ )

TABLE III.—REACTION OF METHYLBUTYL HALOGENOMETHANE WITH SODIUM IODIDE (0.3 MOL./LITRE) IN ANHYDROUS ACETONE AT 50° C.

	$k_2$
Fluoromethane	$1.3 \times 10^{-7}$
Chloromethane	$1.2 \times 10^{-3}$

Iodomethane	$1.4 \times 10^{-1}$

<sup>11</sup> Moelwyn-Hughes, *Chem. Rev.*, 1932, 10, 242; *Kinetics of Reactions in Solution*, Oxford, 1933.

<sup>12</sup> These figures represent preliminary measurements and are not very accurate.

and methylbutyl chloromethane +  $\text{Cl}^-$  are the same, the latter reaction would have (at  $50^\circ$ ) a velocity constant of  $k_2 = 6.8 \times 10^{-7}$ , which at the concentration of 0.036 mol./litre  $\text{LiCl}$ , as used above, would only lead to a measurable decrease of rotation in about one year.

Olson and Long<sup>9</sup> have found the following data for the four reactions of chlorosuccinic and bromosuccinic acid with  $\text{Cl}^-$  and  $\text{Br}^-$  ( $50^\circ$ , aqueous solution, 2 *N*-hydrogen ions).

	Chloride ions.	Bromide ions.
Chlorosuccinic acid	$4.8 \times 10^{-8}$	$2.0 \times 10^{-8}$
Bromosuccinic acid	$1.0 \times 10^{-8}$	$7.0 \times 10^{-8}$

The sequence of these figures is analogous to that given above.

### Experimental Part.

#### Racemisation Experiments.

For the racemisations the experimental procedure was exactly as in our first paper, *i.e.*, to fill up weighed amounts of organic and inorganic halides with anhydrous acetone to 10 c.c. These solutions were filled into water jacketed polarimeter tubes, which were kept in thermostats and were only removed from there for the short times during which readings were being taken.

#### Substitution Reactions.

The substitution reactions were carried through according to the method of Conant and co-workers.<sup>13</sup> Thus the reaction between phenyl methyl chloromethane and sodium iodide was followed by titrating the amount of iodide ions with potassium iodate. By this method both iodide ions and free iodine are titrated; therefore, the iodine set free by decomposition of the phenyl methyl iodomethane formed was determined separately and accounted for by subtracting an equivalent amount from the potassium iodate used.

The isolation of the products of this reaction was carried through by distillation *in vacuo*. The reaction mixture was filtered, evaporated, the residue dissolved in ether, washed with potash solution and water, dried and distilled. The first fraction (b.p.  $33^\circ/14$  mm.) consisted of styrene and ethylbenzene. The styrene always prevailed (normally 70 per cent.), which may be accounted for according to the considerations of Meinert<sup>14</sup> and F. O. Rice.<sup>15</sup> The residue was again dissolved in ether, treated with sodium thiosulphate solution and distilled at 0.1 mm. pressure. The first fraction (b.p.  $40-45^\circ$ ) always showed a dark brown colour which, even after repeated distillations, reappeared. The analysis showed an iodine content of 29.2 per cent. (calculated for  $\text{C}_6\text{H}_5\text{I}$ , 54.8 per cent.). The next fraction (b.p.  $80-110^\circ$ ) showed after distillation the b.p.  $80-84^\circ$  at 0.25 mm. and was according to that boiling-point and the analysis (Found: C, 90.4; H, 9.0. Calculated for  $\text{C}_{12}\text{H}_{18}$ ; C, 91.4; H, 8.6) dimethyl diphenyl ethane in its liquid racemic form.<sup>16</sup>

This experiment has also been carried out using optically active phenyl methyl chloromethane. But since the racemisation of phenylmethyl iodomethane by iodide ions probably occurs some 10,000 times faster than the substitution of the corresponding chloride by iodide ions (compare Table III.), one cannot expect to obtain optically active phenyl methyl iodomethane. Neither this compound nor the dimethyl diphenyl ethane showed a marked optical activity.

<sup>13</sup> *J. Amer. Chem. Soc.*, 1924, **46**, 233; 1925, **47**, 476, 587.

<sup>14</sup> *Ibid.*, 1933, **55**, 979.

<sup>15</sup> *Ibid.*, 1931, **53**, 1959.

<sup>16</sup> Compare Ott; *Ber.*, 1928, **61**, 2124.

The decomposition of phenylmethyl iodomethane described above is analogous to that of triphenyl iodomethane, which splits spontaneously into iodine and triphenyl methyl radicals,<sup>17</sup> the difference being that the free phenyl methyl radical is unstable and partly disproportionates into styrene and ethylbenzene, and partly dimerises into sym. dimethyl diphenyl ethane

### Preparation of Materials.

The preparation of phenylmethyl chloromethane and anhydrous acetone have been described in our first paper. Methylpropyl fluoromethane is prepared in the following way: 14 gms. of silver fluoride are carefully mixed with 42 g. of quartz sand in a mortar and introduced into a reaction flask, stoppered with a rubber stopper with three holes. A dropping funnel is placed into one of the holes, while into the two others glass tubes are fitted for drawing off the fluoromethane formed and introducing nitrogen into the flask. While a slow stream of nitrogen (5-6 bubbles per min.) passes through the apparatus, 20 g. of methylpropyl iodomethane are introduced into the reaction vessel. The reaction occurs immediately, the solid phase turning yellow. The current of nitrogen takes the fluoromethane into a receiver combined from a U-shaped tube heated to 60° C. and a condenser connected with a suction flask cooled to -30°. The U-tube serves for removing the unchanged iodomethane from the reaction products; the fluoromethane is condensed in the receiver (closed by a calcium chloride tube) and is purified by repeated distillation. B.p. 48-50°/756 mm. (Found: C, 67.0; H, 12.3, calculated for C<sub>3</sub>H<sub>7</sub>F: C, 66.7; H, 12.2).

Methylbutyl fluoromethane, prepared in an analogous manner, has the b.p. 60-72°/759 mm.

Methylbutyl chloromethane was prepared according to Levene and Mikeska<sup>18</sup>; for the preparation of the corresponding bromo derivative we used exactly the same method as was described by J. H. Green.<sup>19</sup>

In Tables I. and II. the results of four experiments are given in full; Table III. gives a complete presentation of the graphically averaged constants of all experiments. The notations used are:—

$\alpha$  measured rotation.

$$k_1 \text{ first order constant } k_1 = \frac{\log \frac{\alpha_0}{\alpha_t}}{t}$$

$k_2$  reaction constant for the substitution underlying the racemisation,

$$k_2 = \frac{1}{2} \cdot \frac{k_1}{C_{\text{inorg. halide.}}}$$

$t$  time in minutes.

### Summary.

A kinetic study of the racemisation of methylpropyl iodomethane and of methylbutyl iodomethane by iodine ions in connection with studies of related substitution reactions has brought additional evidence for the theory of substitution of organic halogen compounds by halogen ions.

## AN ELECTRON-DIFFRACTION STUDY OF THE STRUCTURE OF ELECTRO-DEPOSITED METALS.

BY G. I. FINCH AND C. H. SUN, PH.D.

*Received 28th February, 1936.*

### 1. Introduction.

A more or less pronounced tendency for the crystals to orientate in accordance with a position of maximum mechanical stability can generally be observed when a crystalline film is formed by the deposition of crystals upon a substrate. For example, in the case of colloidal solution of graphite, the crystals of which are known to be exceedingly thin in the *c* axial direction but of relatively large cleavage plane dimensions, the particles settle out in such a manner that this plane is parallel to the substrate. On the other hand, when the crystals are formed on the substrate as, for example, by the condensation of vapour or by chemical attack, the substrate may either serve as a virtually inert supporting medium in contact with which the most readily formed external plane of the crystal is developed, or the substrate crystals may themselves govern the orientation of the deposited crystals by determining the type of face first developed on condensation. Many examples are known of the first case which is, in effect, virtually the parallel to that in which already formed crystals take up an orientation imposed by considerations of mechanical stability. Thus, Kirchner<sup>1</sup> found that cadmium iodide formed by the condensation of the vapour on a celluloid film was orientated with the (001) planes parallel to the support, and even more striking was Jenkins'<sup>2</sup> observation that the crystalline oxide scums on molten lead, tin, zinc and bismuth displayed similar orientation effects. Examples of the substrate playing the much more active rôle of causing the deposit crystals to adopt the orientation of those of the substrate are less frequent, but well-authenticated cases of crystals being constrained by the substrate into taking up unusual modes of orientation are known. Thomson,<sup>3</sup> for example, showed that silver electro-deposited on an etched copper cube face rigidly followed the orientation of the copper ;

<sup>2</sup> Jenkins, *Proc. Physic. Soc.*, 1935, 47, 109.

<sup>3</sup> Thomson, *Proc. Roy. Soc.*, 1931, A133, 1.

and Finch, Quarrell and Wilman<sup>4</sup> found that crystals formed by the cathodic sputtering of gold under conditions favourable to the production of a random film exhibited (111) orientation when deposited on platinum of similar orientation, but were randomly disposed when grown on a glass surface. Even more intense are substrate effects such as those giving rise to the phenomenon of pseudomorphism<sup>5</sup> and the dissolution of crystalline metal films in the polish layer on metals.<sup>6</sup>

Jenkins<sup>7</sup> and Finch, Quarrell and Wilman<sup>4</sup> have drawn attention to the fact that a film of orientated graphite crystals adheres much more strongly to a substrate than does a similar but unorientated layer, and Finch, Quarrell and Roebuck<sup>6</sup> remarked that certain metal films formed by condensation of the vapour are firmly held only by a polished but not by a crystalline metal substrate. On the other hand, as far as we are aware, the effect on the adhesion of a deposit, the crystal orientation of which has been determined by that of the substrate, has not been examined.

Some of the problems hinted at in these introductory remarks have already been the subject of study by X-rays.<sup>8</sup> The limitations of this method, however, when applied to such cases of surface phenomena are obvious. Thus, our interest centres in the main about the region of contact between substrate and deposit; and a probable change between abnormality in, for example, the orientation in the first deposit layers and a more usual type of orientation possibly reverted to with growing film thickness might well escape detection by X-rays, particularly if the change were at all rapid. On the other hand, the subject is one which appears eminently suitable for study by the method of electron diffraction.

The object of the experiments described below was to study by electron diffraction surface orientation effects and their associated phenomena as exhibited by electro-deposited metal films, not only at grazing incidence but also by transmission. In addition to preparing specimens mounted on massive substrates and therefore only suitable for examination at grazing incidence, we have been able to devise methods for producing robust metal films, by either electrodeposition or chemical displacement, which were sufficiently thin for transmission purposes and consisted, as desired, of the deposit either alone or together with the substrate. We have found, *inter alia*, that whilst in the case of chemical deposition the change from substrate to deposit is a gradual one of alloying, in electrodeposition the composition change is abrupt, though the substrate orientation nearly always profoundly affects that of the initial deposit layers. In certain cases, characterised by inability of the substrate to impose a definite orientation on the crystals in the deposit, poor adhesion was observed.

## 2. Preparation of Reflection Specimens.

The metal to be examined was electrodeposited either on to a metal layer previously deposited on a suitable metal disc, such as copper, or directly on to the disc. After plating, the specimen was washed with

### 3. Orientation in the Absence of Substrate Effects.

Preliminary experiments were carried out with the main object of determining the normal type of crystal orientation assumed in the various metal films formed under the electrodeposition conditions outlined in Table I. Amorphous or polished metal substrates were used in order to preclude as far as possible any specific orientating influence such as might possibly be exerted by the crystalline substrate. The results obtained are summarised in Table II., and typical patterns illustrating some of the more striking orientation effects are produced in Figs. 1, 2 and 3. As previously,<sup>4</sup> we continue to define the direction of orientation in terms of the indices of planes parallel to the substrate surface or specimen film.

In the case of zinc, evidence was obtained of the layers first deposited going into solution in the polished copper surface. Thus, in order to obtain a zinc layer sufficiently thick to afford a pattern recognisable as characteristic of a crystalline structure, it was necessary to deposit from the cyanide bath at 0·08 A./dm.<sup>2</sup> and 20° C. during at least 3 minutes on to a polished copper substrate, whilst 30 seconds sufficed with a crystalline copper substrate, other conditions being the same. In view of the results obtained by Finch, Quarrell and Roebuck<sup>5</sup> in their study of the surface action of the Beilby layer it is quite probable that a similar preliminary solution of deposit in substrate occurred to a greater or lesser extent in the majority of the cases of deposition on polished substrates set forth in Table II. The fact that even the thin deposits on arsenic were for the most part well orientated supports this view and suggests further that the electrodeposited arsenic substrate was not in fact amorphous but consisted rather of exceedingly small crystals.

The types of orientation set forth in Table II. and exhibited by thin

layers on arsenic and by all the thick deposits may be taken as normal and representative of the plating conditions outlined in Table I. In some cases, for example,  $\alpha$ -brass and gold, where in the same specimen some crystals exhibited one and others another direction of orientation, the second type of orientation has been traced to bath concentration changes occurring during deposition. Thus, a fresh gold bath always led to a mixture of (111) and (100) orientated crystals, whilst a partially used bath in which the gold contents had been enriched from the anode yielded crystals of (111) (Fig. 2) orientation alone.

TABLE II.—SUBSTRATE ORIENTATION EFFECTS ON AMORPHOUS SURFACES.

		-Brass	(111)	(111) and (311)

#### 4. Substrate Orientation Effects.

In these experiments a basis metal was electrodeposited on to a polished copper disc either in the form of a thin layer exhibiting random crystal array, or to a thickness such that it showed well the normal type of orientation as set forth in Table II., and the specimen metal was in turn deposited on this basis as substrate, the plating conditions being as given in Table I.

When the substrate consisted of fairly large (50-100 Å) crystals in random array, it was found that thin films of iron on copper and of gold or copper on nickel were unorientated, but displayed their normal characteristic orientations with sufficient thickening of the deposits. Thus, thick iron, gold and copper exhibited (111), (111) and (110) orientations respectively. These results suggested a strong substrate orientating influence on the first deposit layers, because otherwise we would have expected to find similar orientations in both thick and thin deposits. This view was strikingly confirmed by results obtained with deposits on electrodeposited substrates the crystals of which were well orientated. The results are set forth in Table III. and representative patterns illustrating some of the more unusual modes of orientation observed and due to substrate effect are reproduced in Figs. 4, 5 and 6.

The outstanding feature of these results is that the crystal orientations of the thin deposits were abnormal except in those few cases where the substrate orientation followed that of the normal type as taken up by the deposit under the conditions outlined in Tables I. and II., or when either copper or nickel were deposited on iron of normal orientation. Further,

the crystal orientation of a thin face-centred cubic metal layer formed on a substrate of similar structure, but of an orientation not normally assumed by the deposited metal, followed that of the substrate, though sometimes some differently orientated crystals were also formed, as in the case of copper (Fig. 6) and nickel on gold in (111) and copper on platinum, likewise in (111) orientation. With increasing thickness of the deposits the orientation in general tended to become less pronounced, and in the cases of nickel and copper on gold in (111) orientation, where the progressive changes could readily be followed, it was observed that this loss in orientation went so

§ Obtained by depositing a thin layer of nickel on a (111) gold substrate.

|| No pattern could be obtained without interfering with and destroying the surface structure by scratching, etc.

far that the patterns became almost characteristic of a random crystal array. With still further thickening, however, crystal orientation once more became pronounced but was now of the normal type. Estimates based on the deposition conditions showed that the effect of the substrate on the crystal orientation in the deposit could still be detected up to a thickness which depended upon the nature of the metal, but was generally of the order of 1,000 Å., and that the normal type of orientation did not as a rule appear strongly until the deposit had become considerably thicker. The persistence of the substrate influence was most marked with nickel and was somewhat affected by the nature of the substrate, being greatest in the case of gold and decreasing with tin,  $\alpha$ -brass and copper. Even on

gold, however, the substrate effect was completely lost when the nickel deposit thickness was of the order of 2,000 Å.

No substrate orientating influence could be detected with copper or nickel on iron; thus at a thickness estimated at only 50 Å. the normal (110) orientation appeared in both cases.

Unlike the face-centred cubic deposits on face-centred cubic substrates, the body-centred cubic metal, iron, did not follow the substrate orientation, but exhibited nevertheless a strong substrate influence in that the crystal orientation in thin layers was abnormal; in general this was such that the atom population density in the orientation plane of the deposit crystals approached to that of the substrate. This was also the case with tin on gold or copper.

We have examined the adhesion of the deposits enumerated in Table III. by comparing their resistance to abrasion by rubbing between dry fingers. All showed by this rough test good powers of adhesion with the exception of nickel on tin, and bismuth on iron, nickel or copper, all of which rubbed off easily. Thus it would seem that ability to orientate, even in the thin initial layers of an electro-deposit, is of advantage in securing good adhesion.

### 5. The Preparation of Transmission Specimens.

As in the case of the experiments outlined above, the electron diffraction examination of the orientating effects of crystalline substrates have hitherto always been carried out with the beam at grazing incidence on specimens mounted on massive substrates. Certain disadvantages are inherent in this method. Thus there is some degree of uncertainty as to the effective camera length, and the error involved might well tend to obscure any lattice distortion effect produced by the substrate. A further inaccuracy is liable to be introduced by the small height to which the crystals project over the shadow-throwing surface; for it is now a matter of experience that, compared with transmission, "reflection" patterns are often inferior from the point of view of ring sharpness, and in many cases the difference in definition is largely to be ascribed to the relaxation of the Laue diffraction condition corresponding to the direction normal to grazed specimen surface. It was chiefly for these reasons that in continuing this study of substrate effects we turned to the use of transmission specimens.

Two methods for preparing this type of specimen by electro-deposition have been developed and previously described,<sup>4</sup> but have since been considerably improved. In the one, commercial metal leaf floating on the plating bath served as cathode under the conditions outlined in Table I. and was removed from the resulting deposit by submersion in a suitable etching bath. The second method, of more general utility, led to the production of robust transmission specimens which were remarkably uniform in thickness and yielded good diffraction patterns throughout their whole area. In general, the procedure consisted in plating a polished stainless steel disc with a thick layer of some suitable "basis" metal under the conditions outline in Table I. After washing, the disc was further plated with the metal required for examination. The composite basis and specimen metal film was then stripped off the disc and immersed in a reagent to dissolve away the basis metal whilst leaving the specimen metal intact.

In the case of iron, tin, bismuth or arsenic it was found necessary first to plate the steel disc with an exceedingly thin layer of copper or nickel before forming the basis metal film. In this manner iron or tin basis films were deposited on coppered, and bismuth or arsenic on either coppered or nickeled polished stainless steel. The conditions for the electrodeposition of the specimen layer on the basis metal are set forth in sufficient detail in a previous communication<sup>4</sup> and in the further particulars enumerated above in Table I.

After washing to remove the etching reagent, the specimen was picked up on a fine-meshed nickel gauze and transferred whilst still moist to the

camera and rapidly dried by evacuation. The time of deposition varied with the nature of the metal and current density between a few seconds and about 1 minute. The strength of the specimen film depended largely on the bath temperature and current density and also, though to a lesser extent, on the nature and texture of the basis metal layer. Owing to the low current densities employed, the crystal size increased with, and was determined in the main by, the time of deposition. Composite transmission specimens consisting of two electrodeposited metal layers were also obtained by this method, the second metal being either deposited on the first thin specimen layer prior to stripping, or plated on to a floating and previously suitably thinned leaf acting as cathode.

The preparation of transmission specimens by chemical displacement generally involved the prior formation by electrodeposition and isolation of a thin film of the displacing metal, which was then floated on a suitable salt solution of the metal to be displaced. In some cases a relatively thick film was used, and the excess of metal remaining after partial exchange was removed by the appropriate etching reagent.

## 6. Orientation in Composite Transmission Films.

In these experiments the specimens consisted of a metal electrodeposited on a commercial leaf which had previously been suitably thinned for transmission purposes. The results are incorporated in Table IV. and illustrated by the patterns, Figs. 7, 8 and 9, which show that the substrates in most cases consisted of more or less well-developed single crystals.

TABLE IV.—SUBSTRATE ORIENTATION EFFECTS ON ELECTRO-DEPOSITS OF SUPERIMPOSED TRANSMISSION SPECIMENS.

Substrate (Commercial Leaf).	Substrate Crystal Orientation.	Deposit.	Orientation in Deposit.	
			First Direction.	Second Direction.
Pt	(110)	Cu	(110) (Fig. 7)	(110) <sub>Pt</sub> parallel to (110) <sub>Cu</sub>
		Ni	(110) (Fig. 8)	(110) <sub>Pt</sub> parallel to (110) <sub>Ni</sub>
		Co	(110)	(110) <sub>Pt</sub> parallel to (110) <sub>Co</sub>
Pd	(100)	Cu	(100)	(100) <sub>Pd</sub> parallel to (100) <sub>Cu</sub>
		Fe	(100)	(110) <sub>Pd</sub> parallel to (100) <sub>Fe</sub>
Au	(100)	Fe	(100) (Fig. 9)	(110) <sub>Au</sub> parallel to (100) <sub>Fe</sub>
		Co	(100)	(100) <sub>Au</sub> parallel to (100) <sub>Co</sub>
		Ni	(100)	(110) <sub>Au</sub> parallel to (100) <sub>Ni</sub>

These results show that the deposit crystals, like those of the substrate, always exhibited two directions of orientation, at least one of which was common to both substrate and deposit, and the patterns, Figs. 7, 8 and 9, afford convincing evidence of the remarkable degree of faithfulness with which the substrate crystal orientation is followed in these thin films by the deposit. In Figs. 7 and 8, for example, the arcs due to copper and

nickel respectively are virtually exact replicas of the corresponding platinum diffractions, even to the reproduction of minute dots due to larger crystals.

The manner in which the body-centred cubic structure, iron, orientates on a face-centred cubic metal, such as palladium or gold, is of particular interest in that it differs from that encountered in the case of superimposed face-centred cubic structures. Although substrate and deposit crystals continue to possess in common one degree of orientation in that they have similar, *i.e.*, cube, faces in contact, the respective cube edges in the specimen plane are not parallel but inclined at  $45^\circ$  to each other, with the result that (110) and (100) planes normal to the specimen film in substrate and deposit respectively are parallel to each other. This is clearly a case of a substrate influence complied with by the deposit in such a manner as to lead to as strain-free an arrangement of the atoms in the substrate-deposit interface as possible. Thus, in the pattern, Fig. 9, the gold and iron spacings are such that the 200, 220, etc., gold diffractions coincide with 110, 200, etc., of iron respectively, and it is not until the 11th pattern ring that an iron diffraction, the 123 ring, is obtained free from a gold ring. This means that the cube faces of the iron crystals fit closely on those of the gold substrate when cube corner atoms of iron bisect gold cube edges. When given already one common direction, *i.e.*, (100), of orientation, it is clear that no other arrangement will enable the two structures to fit together so accurately without lattice distortion. It may therefore be concluded that this arrangement of substrate and deposit is also the most strain-free. We have, indeed, observed that iron electrodeposited on a massive gold substrate exhibits exceedingly good adhesion.

In the case of iron electrodeposited on palladium, the two structures fit together in a corresponding manner and, although the fit is not so good as in the case of iron and on gold, it is nevertheless still the best possible under the circumstances.

The remarkable pattern of spots immediately surrounding the undiffracted beam spot in Figs. 7 and 8 is a more or less prominent feature in all the patterns obtained from these composite films in which the substrate produced a pattern approaching to the cross-grating type and therefore practically consisted of a single crystal, or at least of closely packed crystals possessing two well-defined directions of orientation in common.

The origin of this central pattern may be deduced as follows: Owing to the thinness of the composite film, the third Laue condition for diffraction is virtually completely relaxed, and we may regard the specimen as consisting of two superimposed cross-gratings, one of platinum,  $a = 3.91 \text{ \AA}$ , and the other of copper,  $a = 3.61 \text{ \AA}$ . Suppose a beam,  $hkl_{Pt}$ , from the first cross-grating be diffracted by the underlying copper film, then a complete copper cross-grating pattern should be ascribed about the  $hkl_{Pt}$  diffraction spot. Thus, as in Fig. 10, there will be a ray, A, diffracted radially inwards and another, B, radially outwards from the central spot, the distance of A and B from  $hkl_{Pt}$  being the radius of the  $hkl_{Cu}$  ring. Similarly, other rays, C and D, etc., will be diffracted in various directions from that of the initial  $hkl_{Pt}$  ray. So far we have only considered a single platinum crystal with its underlying layer consisting of a copper single crystal in similar orientation; but the patterns, Figs. 7 and 8, consist of a series of short arcs, and we must therefore consider the effect of rotating the cross-gratings about the primary beam by an angle equal to the angular extent of the arcs of the normal pattern. Quite clearly the effect upon A and B will be to spread the spots over an angle,  $\alpha$ , subtended by the normal pattern arcs at the central spot. Since A is much nearer the central spot than B, it follows that the same amount of energy will be concentrated into a much smaller area at A than at B. The arc A will therefore be much more intense than B. A similar effect will occur for C and D, but in addition there will be a two-dimensional spreading and consequent blurring of the C and D arcs, owing to the extent of the primary  $hkl_{Pt}$  arc, and we should therefore hardly expect to observe such diffractions in the patterns.

This view, according to which the central pattern is due to double diffraction, is completely in agreement with the facts. Thus, in Fig. 7,

FIG. 10.

the pattern close to the central spot corresponds to a face-centred cubic structure,  $a_0 = 48.9$  Å., in exactly the same orientation as the platinum and copper, and the scattering angle corresponding to each of these inner arcs is the difference between the scattering angles of the corresponding diffractions of the platinum and copper respectively. For example, the radius of the arc ascribed to the  $111$  diffraction from the face-centred cubic structure of cube edge  $48.9$  Å. is equal to the difference between the radii of the  $111$  platinum and copper diffractions respectively. Again, all three arcs fall on the same radius and

have the same angular extent, and whilst the arcs near the undiffracted beam spot are intense, the corresponding arcs described about, and on the opposite side, of the  $111$  platinum diffractions are too weak to be seen in the reproduction, though plainly visible in the original negative.

Similar results obtained with other composite films are set forth in Tables V *a*, *b*, *c*, and *d*. They completely confirm the above double scattering view.

In addition to those shown in Table Va, three other arcs foreign to either platinum or copper were observed in the pattern. Their origin could be traced to double diffraction. Thus, the arc with radius  $1.14$  cms. is due to the diffraction of the  $222_{Pt}$  diffraction by  $(111)_{Cu}$  (calculated  $1.13$  cms.);  $1.43$  cms. arc due to the diffraction of  $111_{Pt}$  by  $(222)_{Cu}$  (calculated  $1.43$  cms.); and  $1.92$  cms. arc due to the diffraction of the  $200_{Pt}$  beams by  $(331)_{Cu}$  (calculated  $1.92$  cms.).

Three other arcs were also observed in the pattern of Table Vb. The arc with radius  $1.03$  cms. is due to the diffraction of  $222_{Pt}$  by  $(111)_{Ni}$  (calculated  $1.02$  cms.);  $1.40$  cms. arc due to the diffraction of  $111_{Pt}$  beam by  $(222)_{Ni}$  (calculated  $1.40$  cms.); and the  $1.98$  cms. arc due to the diffraction of the  $311_{Pt}$  beams by  $(440)_{Ni}$  (calculated  $1.97$  cms.).

The occurrence of this phenomenon of double scattering is of particular importance in connection with the general interpretation of the relative intensities of the diffractions in electron diffraction patterns. In the case of a specimen consisting, for example, of a chaotic aggregation of the same type of crystals, the effect must give rise to an anomalous intensity distribution, in that it will have the tendency to even out the intensity differences between the various diffractions.

## (d) Cobalt on Platinum.

Faint, diffuse double diffraction pattern observed near and around the central spot.

In the examples of double scattering set forth above, the relationship between substrate and deposit crystal orientation was so intimate that the specimens could be regarded as being virtually single structures but characterised by an abrupt change of lattice constant occurring at a sharply defined boundary within the structure. We should therefore expect to find similar intensity-levelling double-scattering effects even in the case of single crystal transmissions of the cross-grating type. The effect must occur; otherwise it would be difficult indeed to account for the exceptional intensity of the higher order diffractions which is so characteristic of the electron diffraction cross-grating pattern. Thus, it is by no means unusual to record as many as 15 orders in a mica transmission. Beeching<sup>9</sup> has observed a similar effect in the case of the reflection of electrons from a natural diamond face, and other investigators, notably Raether,<sup>10</sup> have recorded similar anomalies. Bethe's<sup>11</sup> dynamical treatment neglects the experimental fact of the co-existence of several strong diffracted beams and their consequent interactions and must therefore be inadequate in its present form as a guide to the quantitative interpretation of intensity distribution. The need for caution at the present time in assigning anything more than a general qualitative significance to intensity measurements of electron diffraction patterns is evident.

## 7. Orientation Changes Subsequent to Substrate Removal.

Experiments were carried out with the object of seeing to what extent, if any, the orientation of the deposit crystals might be affected by the removal of the substrate. That such an effect can and does occur is strikingly demonstrated by the patterns, Figs. 9, 11 and 12. Thus, in Fig. 9, from iron electrodeposited on gold, the arcing shows that both metals were in cube face orientation and with an iron cube face parallel to gold cube-diagonal planes. This specimen was next floated, gold downwards, for a few seconds on a weak cyanide solution and re-examined after washing. The resulting pattern, Fig. 11, shows that much of the gold had gone into solution, and that the arcing of the rings has become much less distinct than previously in Fig. 9. After further etching, leaving only a trace of gold, the pattern, Fig. 12, was obtained. The rings are now practically free from arcs, thus showing that with removal of the substrate the second direction of orientation of the iron crystals has been lost. Furthermore, the intensity distribution is now such as to suggest that what slight degree of orientation still remained was (110) rather than (100) parallel to the specimen plane. It is probable that the loss in orientation was due to crinkling of the iron film on removal of the substrate.

We have in other cases observed distinct signs of similar changes due to removal of the substrate influence, but in none were the effects so clearly in evidence as with iron on gold.

## 8. Substrate Influence on Crystal Size.

An example of the effect of the substrate structure on the crystal size of a deposit has previously been given in the case of chromium electrodeposited on copper, nickel, iron, tin and bismuth substrates.<sup>4</sup> The size of the deposit crystals appeared to be determined mainly by the crystal size in the substrate, provided the deposition conditions were otherwise the same. Nickel seemed on the whole to be less susceptible than chromium to this specific substrate influence, and generally gave patterns which are remarkable for their clarity and ring definition. Electrodeposited on amorphous arsenic, however, even nickel exhibited a pronounced tendency to form small crystals.

## 9. Transmission Specimens of Single Metals.

These specimens were prepared in the manner outlined in Table I. and § 5, and had been electrodeposited on basis metals with normal crystal orientations characteristic of the deposition conditions previously outlined. After stripping and removal of the basis metal the films yielded excellent patterns, representative examples of which have previously been reproduced.<sup>4</sup> It will suffice to recall that it was found that body-centred cubic structures such as iron and chromium tended towards {111}, and the face-centred cubic metals towards {110} orientation.

## 10. Metal Films formed by Chemical Displacement.

A copper film, either commercial leaf or electrodeposited, rapidly whitened when floating on a 1.0 per cent. acid platinum bi-chloride solution. After immersion in 3*N* nitric acid to remove any unattacked copper, the film yielded a face-centred cubic pattern. Double-shutter comparison with gold showed that the film formed by displacement had lattice constants intermediate between those of platinum and copper, and this was independently verified by the pattern, Fig. 13, obtained from a similar platinum-displaced-by-copper film superimposed on gold.

Similar results were obtained with platinum, displaced by floating a silver film on the platinum salt solution, followed by washing with a dilute ammonia solution and 1½ hours' treatment in 3*N* nitric acid to remove

silver chloride and unattacked silver. A typical double-shutter pattern with gold is shown in Fig. 14, from which it will immediately be evident that the lattice constants of the displaced film lay between those of platinum and silver. This film gave a positive test for silver with *p*-dimethylamino-benzal-rhodamine, and the two platinum-displaced-by-copper specimens, on testing for copper with sodium-diethyl-dithio-carbamate also yielded a similar result.

The lattice constants of the 20 copper-platinum specimens examined lay between 3.71 and 3.77 Å. Similarly, in the case of platinum displaced by silver, the lattice constants were found to vary between 3.97 and 4.05 Å, and it was observed that the lattice constant decreased with the time of contact of the silver with the platinum solution. Thus, the chemical and structural evidence both show that copper-platinum and silver-platinum alloys are formed when thin copper and silver films chemically displace platinum, a result which is in sharp contrast to that obtained in the case of electrodeposited single and double films, where no signs of alloying could be detected.

### Summary.

The structure of electrodeposited and chemically displaced metal surfaces and films has been studied by the method of electron diffraction.

It has been found that the structure of the substrate upon which a metal is electrodeposited nearly always profoundly affects that of the deposit, in that the orientation of the substrate crystals determines that of the deposit. In those few cases where the effect did not occur the deposit generally exhibited poor powers of adhesion.

Anomalous diffraction effects, shown to be due to secondary elastic scattering, have been obtained, and the bearing of this phenomenon on the interpretation of electron diffraction pattern intensities has been discussed.

It has been shown that, unlike in electrodeposition, chemical displacement of one metal by another leads to the formation of an alloy.

In this communication we have confined ourselves to setting forth the facts brought to light in the course of experiments and to drawing therefrom the outstanding conclusions of fact. We are deferring a more detailed discussion until the completion of further work which is now in hand.

We wish to thank the Government Grant Committee of the Royal Society and Messrs. Ferranti Ltd. for grants for apparatus.

# THE DIFFRACTION OF ELECTRONS BY AMALGAM FILMS.

BY A. E. AYLMER, G. I. FINCH AND S. FORDHAM.

*Received 6th March, 1936.*

## § 1. Introduction.

The occurrence of isolated so-called "extra" or "forbidden" rings in electron diffraction photographs, more particularly from metal films and surfaces, has long been noted. Such rings were obtained in profusion by Finch, Quarrell and Wilman<sup>1</sup> from both beaten and electrodeposited metal foils, and more especially from such films after heating in contact with various gases followed by rapid quenching to room temperatures. In addition to "extra" rings, these experiments also often led to the appearance of remarkable band systems which were interpreted as evidence of a gradual lattice expansion with entry of gas. These results suggested that the diffraction of high speed electrons might afford a powerful and direct means for investigating the interaction of gases and solids. For the successful prosecution of such a study, however, it would be essential to exclude the formation of "extra" rings due to causes other than gas absorption, or at least to be able to recognise the origin of such rings when they do occur.

Mark, Motz and Trillat<sup>2</sup> have shown that traces of grease can give rise to a well-marked group of "extra" rings in patterns from metal films and also from cellulose. The corresponding spacings, however, have been found to be independent not only of the nature of the metallic or cellulosic substrate but also of the types of grease so far found to occur as adventitious impurities in the laboratory. "Grease" ring systems should therefore not be difficult to recognise. Furthermore, by taking suitable precautions the formation of such contaminating grease layers can be suppressed; also, as Trillat<sup>3</sup> has pointed out, the grease can generally be removed by washing the specimens with suitable solvents.

Finch and Quarrell<sup>4</sup> have recently recorded the fact that amalgamation can give rise to "extra" ring systems which, unlike the grease rings, have spacings dependent upon the metal and are thus more difficult to distinguish from absorbed gas rings than are the grease rings with their constant spacings. The following experiments were therefore carried out with the object of elucidating the structure of thin gold, silver, copper and palladium foils after attack by mercury under conditions which could be considered as representative, even though possibly exaggerated, of adventitious contamination of such films in the laboratory.

## § 2. Experimental.

Gold, silver, palladium and copper were supplied in leaf form by Messrs. G. M. Whiley Ltd. The gold was described as "fine gold, guaranteed absolutely free from alloy." After thinning by floating on a  $N/50$  potassium cyanide solution, followed by washing in distilled water, it gave diffraction patterns characteristic of the pure metal, except that in addition to the normal rings at least two "extra" rings corresponding to spacings of  $4.44$  and  $2.56\text{\AA}$ . were more or less faintly discernible in the majority of specimens taken from three books of two different batches. It will be seen later that these "extra" rings were due to traces of amalgamation. The gold crystals were generally orientated with (100) planes parallel to the film (complete rings with the specimen normal to the beam, but the 200 very strong and 111 abnormally weak) and frequently a second common direction of orientation was also more or less in evidence, the rings tending to break up into arcs. The "extra" rings, however, were always continuous.

According to Messrs. Whiley, silver does not beat into a fine leaf unless of a high grade of purity. The leaf supplied assayed over 99.9 per cent., the chief impurity being copper with traces of arsenic and lead. The cyanide-thinned and washed leaf gave the normal silver pattern, usually free from any signs of "extra" rings. In most specimens the crystals were orientated in the manner observed in the case of gold, the diffraction rings being more or less strongly reed.

The palladium leaf was beaten from a high grade metal obtained from the Mond Nickel Company. It was thinned by floating on a solution of concentrated nitric acid in an equal volume of water and washed as above. The patterns were characteristic of palladium and free from "extra" rings. The crystals were more highly orientated than in the case of gold or silver, and many specimens yielded a nearly perfect cross-grating pattern characteristic of cube face orientation.

The copper leaf had been beaten from electrolytic metal and contained only traces of impurities, chiefly lead and arsenic. It was thinned with an acidified solution of ammonium persulphate or with a 20 per cent. potassium cyanide solution and washed. The patterns were typical of copper, though occasionally a much fainter secondary ring system due to cuprous oxide appeared.

Amalgamation was carried out by hanging a  $3 \times 1.5$  cm. strip of the thinned leaf above a warmed drop of mercury until the lower edge had been whitened, in the case of gold, or become brittle and frosty in appearance in the case of silver. Palladium showed no visible signs of attack even after prolonged exposure leading to condensation of mercury on the leaf. Copper amalgam specimens prepared in this manner were found to be unsuitable for electron diffraction.

Amalgamation was also carried out by electrodeposition and by chemical displacement. Thus gold leaf was amalgamated by using it as a cathode in a nearly saturated mercuric chloride bath with a mercury anode. By varying the current density and times of deposition a wide control of the extent of amalgamation could be effected. Silver amalgams were similarly prepared with mercuric chloride and nitrate baths. Finally, silver and copper amalgams were obtained by merely floating the leaf on such baths, the extent of attack being controlled by the time of contact.

## § 3. Gold Amalgams.

The gold leaf specimens attacked by mercury vapour exhibited all shades of colour from that of pure unalloyed gold to the metallic white of the mercury-rich amalgam formed at the lower edge of the leaf. The transition from yellow to white occurred rapidly, however, and was confined as a rule to a strip of about only 1 mm. width. Diffraction patterns were taken from several places in and on either side of this transition zone.

Patterns from the gold side were characteristic of gold except for the appearance of two comparatively strong amalgam rings lying inside the 111 gold diffraction and corresponding to spacings of 4.44 and 2.56 Å., and which are nearly always visible in most gold leaf patterns. Although the gold rings were arced, the amalgam rings were always continuous. On progressing towards the mercury-rich end of the specimen, these "extra" rings became more and more prominent (Fig. 1), many new rings appeared and, with further approach to the most heavily amalgamated area, some of these in turn disappeared whilst others became stronger until the gold pattern was completely displaced by a fully developed amalgam ring system which must be due to a well-crystallised gold-mercury alloy (Fig. 2). The spacings corresponding to the gold amalgam rings, referred to gold,

TABLE I.—GOLD AMALGAM ( $a_{Au} = 4.070 \text{ Å.}$ ).

Spacings, Å.	Ring Intensities.	Assigned Indices.	Spacings Calculated for a Simple Cubic Lattice, $a = 17.81 \text{ Å.}$

In column 2 the diffracted intensities are recorded as v.s. = very strong, s. = strong, m.s. = medium strong, m. = medium, f.m. = faint to medium, f. = faint and v.f. = very faint; d. signifies diffuse.

as to render it difficult to assign definite structures to the intermediate alloys. Further, out of 20 patterns yielded by incompletely amalgamated gold specimens, no two patterns containing four or more amalgam rings agree throughout either in ring diameters or intensities, a fact which testifies to the remarkably wide range of structures to be met with in the incompletely amalgamated gold specimens.

The amalgams formed by the electrodeposition of mercury on a gold leaf cathode were prepared with the object of obtaining evidence of the possible formation of amalgams differing from the above structure observed when the leaf had been fully attacked at room temperature by mercury vapour. Though in all 15 such specimens, representative of a wide range of colour between gold and mercury-white were prepared, the resulting patterns confirmed in every relevant detail the results obtained in the case of attack by mercury vapour.

$a_{Au} = 4.070 \text{ Å.}$ , are given in Table I. The best fit we have been able to find is given by a simple cube of  $a = 17.81 \text{ Å.}$  No space-group can be assigned, as the pattern does not afford sufficient information, and we have not succeeded in obtaining single crystal patterns.

It seems likely that the mercury-richest of the gold amalgams was also the most stable of those examined. Thus several rings, notably the two very intense ones corresponding to 4.44 and 2.56 Å. which were the first to appear in the initial stages of amalgamation, persisted right through into the patterns from the fully amalgamated specimens; whilst the appearance and disappearance of other rings with progressing amalgamation afforded evidence of the transitory formation of a wide range of intermediate alloys. The complexity of the corresponding patterns is such

In addition to the above outlined methods of preparing gold amalgam, we have found that heating a partially amalgamated gold film to a sufficiently high temperature in vacuo leads to the formation of the amalgam structure described in Table I. Thus, a fresh gold leaf specimen which only faintly showed the two normally most prominent amalgam rings, after 15 mins. heating in vacuo at  $720^{\circ}$  yielded a pattern similar to Fig. 2 and without any trace of gold rings. The pattern could only be obtained, however, from a few small areas of the specimen, the heat treatment having otherwise resulted in the collapse of most of the gold film previously bridging the meshes of the supporting gauze, probably as a result of melting. Thus Faraday<sup>5</sup> found that a continuous gold film on glass gathered up into minute globules on heating at  $300^{\circ}$ . Hence it seems that, from the point of view of electron diffraction, the gold is destroyed as a specimen by a heat treatment which is successfully resisted by the amalgam films. This and other similar results are of importance in connection with the study of the absorption of gases by metallic foils, in that they show how easily an originally practically negligible concentration of amalgam may virtually increase, as a result of heating, to such an extent as finally to predominate in imposing its character upon the diffraction pattern.

These experiments were repeated with fresh gold films formed by electro-deposition in the manner previously outlined.<sup>11</sup> Such films proved to be free from mercury in that they afforded no trace of amalgam rings even after prolonged heat treatment, provided this was carried out in a vacuum free from mercury vapour.

Pabst<sup>6</sup> and Stenbeck<sup>7</sup> have investigated the gold-mercury system by means of X-ray diffraction, using carefully annealed specimens. No agreement has been found between their results and those obtained in these experiments.

#### § 4. Silver Amalgams.

It was not easy to obtain sufficiently robust and yet not too dense amalgamated silver specimens by mercury-vapour attack of suitably thinned leaf, largely owing to the patchy and uneven thickness of the raw leaf. Also it was more difficult than in the case of gold to distinguish visually the transition between the fully amalgamated to un-attacked silver. As before, however, patterns were obtained through areas likely to be representative of progressive attack by gradually working from the upper to the lower leaf edge. After slight amalgamation, two fairly prominent continuous amalgam rings with spacings of 2.92 and 2.44 Å. appeared within the silver 111 diffraction.

<sup>7</sup> Stenbeck, *Z. an. all. Chem.*, 1933, 214, 16.

The analysis of Fig. 3 is given in Table II. A reasonably good fit is given by a face-centred tetragonal structure,  $a = 6.93$  and  $c = 5.82$  Å.

The structure assigned above should give a 200 diffraction; its absence, however, might well be due to a general tendency of the crystals to orientate with (100) planes parallel to the specimen plane. This view is borne out by the pattern, Fig. 4, in which, however, in addition to the rings corresponding to the spacings set forth in the first column of Table II, there appears a ring of medium intensity with the spacing  $3.43$  Å., the theoretical value for 200 indexing being  $3.46$  Å. In this case the silver specimen had been prepared by electrodeposition from a cyanide bath and had (110) orientation before amalgamation.

The initial stages of amalgamation by electrodeposition of mercury on silver from mercuric nitrate were found to be marked by the appearance of two prominent "extra" rings inside the 111 diffraction and with spacings nearly similar to those first developed in the early stages of the amalgamation of gold. After electrodeposition at  $0.1$  A./dcm. during 40 seconds, a pattern containing only amalgam rings was obtained. The analysis is

given in Table III, from which it will be seen that this silver amalgam is closely similar to that obtained from gold amalgamated by mercury vapour, Fig. 2, and thus has a structure practically identical with that of the final gold amalgam; indeed, owing to the similarity between the lattice constants of gold and silver, it would be difficult to distinguish between the two amalgam patterns without double-shutter measurements.

An amalgam of similar structure was also obtained by displacing silver from a nearly saturated silver nitrate solution by a drop of mercury. The resulting amalgam after washing and supporting on a collodion film spanning nickel gauze gave a pattern similar to that analysed in Table III.

Silver leaf after floating on a nearly saturated mercuric chloride solution during three minutes gave complex ring patterns containing no silver rings. The analysis of the representative pattern, Fig. 5, is set forth in Table IV. Similar patterns were also occasionally obtained from specimens amalgamated by electrodeposition. We have so far not succeeded in clearly defining the conditions of electrodeposition leading to either this or the former type of amalgam yielding a pattern similar to that analysed in Table III.

Hence the structure of this silver amalgam was probably face-centred tetragonal,  $a = 9.05$  Å.,  $c = 5.62$  Å.,  $c/a = 0.62$ , and thus differed entirely from that of the gold and the two silver amalgam structures described above.

The commercial silver leaves used in these experiments were as a rule less contaminated by traces of mercury than the gold. Thus it was only in exceptional cases that the  $4.48$  and the  $2.57$  Å. amalgam rings were visible in a pattern from the fresh leaf, and then only faintly. Nevertheless,

even in the case of a leaf which initially had yielded a normal silver pattern free from amalgam rings, heating at  $190^{\circ}$  during 15 minutes in a mercury-free vacuum maintained by an oil vapour pumping equipment led to the appearance of many amalgam rings corresponding to the spacings given in Table III; indeed, many of these amalgam rings were obtained from a specimen after heating at only  $140^{\circ}$  during 15 minutes (Fig. 6); after 2 minutes at  $600^{\circ}$  the original silver pattern had been displaced by a pattern virtually identical with that from which Table III was compiled. In this case it is possible that the concentration of the slight traces of amalgam which must have been present in the original leaf was due to the evaporation of the silver rather than to the disruption of the film by fusion, because it is well known that thin silver films sublime readily at temperatures in excess of about  $300^{\circ}$ .

As in the case of gold, X-ray investigation of the silver-mercury system by Murphy and Preston,<sup>6</sup> Stenbeck,<sup>7</sup> and Weryha<sup>8</sup> has yielded results which differ from those recorded above

### § 5. Copper Amalgams.

The copper leaf used in these experiments, after thinning by floating on an acidified ammonium persulphate bath, followed by a cyanide bath to remove cuprous oxide and a final washing in distilled water, gave patterns characteristic of copper, nearly in the form of a thin single crystal in (110) orientation, together with the 111 diffractions of cuprous oxide

TABLE V.—COPPER AMALGAM.

1.71	m.
1.31	f.

The pattern, Fig. 7, obtained with the specimen plane inclined to the beam, shows the result of initial amalgamation effected by floating the thinned leaf on a nearly saturated mercuric chloride solution during 5 seconds, followed by washing in a cyanide bath and in distilled water. In addition to numerous fainter arcs superimposed on the copper pattern, a prominent arced amalgam ring corresponding to a spacing of 2.86 Å. appeared in the earlier stages of attack. The nature of the arcing shows that the amalgam crystals had one common preferred direction of orientation as compared with the two possessed by the original copper specimen; this is confirmed by the pattern, Fig. 8, obtained after complete

<sup>6</sup> Murphy and Preston, *J. Inst. Metals*, 1931, 46, 501.

<sup>8</sup> Weryha, *Z. Krist.*, 1933, 86, 335.

amalgamation with the specimen plane normal to the beam. The 2.86 Å. ring is now exceedingly intense and by far the strongest diffraction in the pattern, which contains no copper rings. The spacings and ring intensities are given in Table V. In view of the relatively few diffractions recorded no significant structure can be assigned.

### § 6. Palladium.

The thinned palladium leaf gave good diffraction patterns in which the short arcs and faintness of the 111 diffractions testified to two well-marked degrees of orientation with (100) faces in the specimen plane, the individual crystals aligning up towards the formation of a single crystal.

It might have been thought that, like platinum, palladium would not be affected by mercury at room temperature. The patterns obtained from the leaf after progressive exposure to mercury vapour, however, afforded ample evidence of some form of attack. The initial stage (Fig. 9) was

characterised by the appearance of three rather diffuse rings of which the middle and most intense was just within the 111 palladium diffraction. In the later stages of amalgamation these diffuse rings became sharper and showed signs of resolution into several rings, whilst new and sharp rings appeared for the first time. Finally, the last stage of attack corresponding to saturation of the leaf with mercury was characterised by a multi-ringed pattern superimposed on the normal palladium arc pattern which unlike in the cases of gold, silver and copper, *i.e.* all metals which amalgamate readily, persisted throughout (Fig. 10). Owing to the complexity of this final palladium amalgam ring system no definite structure can be assigned at this stage.

The fact that even a palladium leaf which had been exposed to mercury vapour until completely covered by condensed mercury and then kept in this stage for several hours before examination always gave a far stronger palladium than amalgam pattern suggests either that the attack by mercury

consisted in a surface absorption, rather than in a real amalgamation of palladium itself, or that the amalgam rings are to be ascribed to the amalgamation of impurities contained in the palladium. It is true that the patterns from the fresh palladium leaf showed no trace whatever of any foreign crystal structure, but it may well be that amalgamation suffices to bring into evidence impurities otherwise too slight in amount to affect the main diffraction pattern. The spacings corresponding to the amalgam rings are given in Table VI, referred to palladium,  $a_{Pd} = 3.882$  Å.

### § 7. Amalgamation in the Diffraction Camera.

It is now a matter of experience in this laboratory that gold and silver, and possibly also other metals, are prone to amalgamation in an electron diffraction camera evacuated by a mercury vapour pump, no matter whether provided with a liquid-air trap or injector system, particularly when they are in the form of transmission specimens and thus open to attack from two sides.

As a rule with gold the first signs of amalgamation, in the shape of the faint appearance of the most prominent amalgam ring or rings, generally become visible after the specimen has been in the evacuated diffraction camera during about 1 hour; amalgamation then proceeds slowly until, after between about 1 and 2 days' sojourn in the evacuated camera, a gold specimen is usually completely amalgamated. In most cases such slow amalgamation is immaterial because the specimen seldom remains in the

camera during more than 10 or 15 mins. When, however, the specimen is being subjected to some special treatment, such as heating in contact with a gas, either *in situ* in the camera or elsewhere, and which calls for its frequent re-examination, amalgamation may well occur to such an extent as to obscure the issues. Hence in all such work it is essential to conduct the structural examination in a mercury-free vacuum. Two cameras,<sup>10</sup> the one depending for evacuation upon oil vapour pumps alone, the other upon an oil vapour backed by a mercury vapour pump, are available in this laboratory for this purpose and prolonged tests have now shown that no amalgamation of the specimen occurs in either.

### § 8. Conclusions.

It was pointed out in §1 that the main object of these experiments was to obtain the information necessary to permit of the recognition of the so-called "extra" ring systems due to adventitious amalgamation as and when they might occur in patterns obtained from metal specimens heated in contact with gases. The results set forth above, however, make it abundantly clear that amalgam ring systems are in general of such complexity and vary so much between themselves according to the extent to which amalgamation may have proceeded that, unlike grease rings, their identification must always be a matter of uncertainty. Accordingly, in studying by electron diffraction the absorption of gases by metal films and surfaces, it is clearly essential to commence with mercury-free specimens which, as pointed out above, can always be obtained by electrodeposition under suitable conditions,<sup>11</sup> and to conduct the further treatment and examination in a mercury-free atmosphere. As a check on the realisation of such conditions, it is now our custom to carry out blank heating experiments and structure determinations with mercury-free transmission specimens of electrodeposited gold, as this metal is the most prone to amalgamation of those which we have so far studied.

### § 9. Summary.

Amalgams of gold, silver and copper and also the effect of mercury vapour on palladium leaf have been studied by electron diffraction.

It has been found that gold and silver readily form a wide variety of amalgam structures of which three have been successfully analysed. Thus gold and silver both form simple cubic amalgams  $a = 17.81$  and  $17.94$  Å. respectively; and two other silver amalgams, both of face-centred tetragonal structure, have also been recognised. Copper also amalgamates readily, particularly during the chemical displacement of mercury, but the structure of the most characteristic amalgam thus formed has not been identified. Palladium is only partially attacked by mercury.

The occurrence and prevention of adventitious amalgamation during the electron diffraction examination and heat treatment of metallic specimens has been discussed.

We wish to thank the Government Grant Committee of the Royal Society and Messrs. Ferranti, Ltd. and Imperial Chemical Industries, Ltd., for grants and apparatus.

# A NOTE ON THE THEORY OF VISCOSITY OF LIQUIDS.

BY D. B. MACLEOD, M.A., D.Sc.

*Communicated by* ERIC K. RIDEAL.

*Received 9th March, 1936.*

Andrade<sup>1</sup> has developed a theory of the viscosity of liquids in which he arrives at the equations

$$\eta v^{\frac{1}{2}} = A e^{c/T^0}$$

and

$$\eta v^{\frac{1}{2}} = \frac{A'}{\sqrt{K}} e^{c'/T^0}$$

where  $\eta$  is the viscosity of a liquid,  $v$  the specific volume,  $K$  the compressibility and  $A$ ,  $A'$ ,  $c$  and  $c'$  are constants. The approximate formula  $\eta = A e^{c/T}$  has been proposed independently by several authors.

The author has shown<sup>2, 3</sup> that the viscosity of a liquid can be represented as a function of the free space. Thus if  $v$  is the specific volume of a liquid and  $b$  the constant volume occupied by the molecules, then

$$\eta = \frac{c}{(v - b)^n} \text{ where } c \text{ is a constant.}$$

For non-associated liquids  $n$  approximates to unity but is much greater than unity for liquids usually regarded as associated.

Evidence was brought forward<sup>3</sup> to show that the constant  $c$  contained the molecular weight as a factor. The departure of  $n$  from unity was interpreted as being due to a certain degree of association in all liquids, which changes with rise of temperature, resulting in a change of the effective molecular weight. The equation

$$\eta = \frac{KM \cdot \alpha}{v - b}$$

was suggested, where  $M$  is the ordinary molecular weight of the substance and  $\alpha$  a quantity greater than unity, depending on the degree of association and, in general, decreasing with rise of temperature.

It is proposed to show that an equation of the type of Andrade can be developed from the above equations.

## The Internal Pressure of a Liquid.

The quantity,  $v - b$ , is intimately connected with the internal pressure of a liquid, by van der Waals' equation

$$(p + \pi)(v - b) = RT$$

<sup>1</sup> *Phil. Mag.*, 1934, 17, 497 and 698.

<sup>2</sup> "On a relation between the viscosity of a liquid and its coefficient of expansion," *Trans. Faraday Soc.*, 1923, 19, 6.

<sup>3</sup> "On a relation between the viscosities of liquids and their molecular weights," *ibid.*, 1925, 21, 151.

For a liquid below its boiling-point, the external pressure  $p$  is negligible compared with the internal pressure  $\pi$ , so that, under these conditions we can write

$$\pi = \frac{RT}{v - b}$$

Van der Waals suggested  $\pi = \frac{a}{v^2}$  to cover the changes of  $\pi$  with change of volume. Most authors have found it necessary to make  $a$  a function of temperature. Berthelot writes  $\pi = \frac{a}{Tv^2}$  and Clausius  $\pi = \frac{a}{T(v + c)^2}$ . None of these quantities when equated to  $\frac{RT}{v - b}$ , gives a satisfactory agreement over any considerable range of temperature.

The author suggests the expression  $\pi = \pi_0 e^{c'/T}$  for the internal pressure of a liquid on the following general argument. The equation  $\pi = \frac{a}{v^2}$  assumes that, at any moment, all the molecules are contributing equally to the internal pressure. It is plausible to regard the internal pressure as being almost entirely due to those molecules which, on account of their temporary low velocities—following the Maxwell distribution of velocities—have coalesced with other molecules or are in very close association with them. The internal pressure between two such molecules would be very great compared with that between two average molecules and might correspond to the internal pressure between two molecules in the solid form. It could, in fact, be represented by some constant quantity  $\pi_0$ . The total internal pressure would then be  $\pi_0$  multiplied by the number of molecules at any given temperature momentarily in this condition. The number of such pairs, following Maxwell's law, would be an exponential function of the temperature, decreasing with rise of temperature. As a liquid can be solidified by pressure alone, the number would also be a function of the volume. Over the range from the melting-point to the boiling-point, for most liquids, a simple inverse function expresses the facts. The internal pressure of a liquid, from this point of view, is a very generalised type of chemical action, with a very low energy change between a state of combination and a state of freedom. It is only possible under highly compressed conditions, which explains its dependence on volume as well as temperature.

It is proposed to write, therefore

$$\pi_0 e^{c'/T} = \frac{RT}{v - b} \quad . \quad . \quad . \quad . \quad (1)$$

for the change of volume of a liquid with temperature. This expression contains three unknowns, namely  $\frac{\pi_0}{R}$ ,  $c'$  and  $b$  and is of a form that can only be solved by trial and error. The value of  $v - b$  in this equation is identical with that calculated from the equation

$$\eta = \frac{c}{(v - b)^n}$$

The application of equation (1) will be illustrated by octane, for which liquid the experimental data are available over a large range of temperature.

In the previous paper<sup>2</sup> the value of  $(v - b)$  at  $0^\circ \text{C.}$  for octane, calculated from the equation  $\eta = \frac{c}{(v - b)^n}$  is given as 0.0940.

Substituting this value of  $v - b$ , in equation (1) virtually reduces the unknowns to two.

Thorpe and Rodger<sup>4</sup> give the following equation for the specific volume of octane.

$$U_t = 1 + 0.02118304t + 0.06186648t^2 + 0.0712947t^3.$$

Table I., column II., gives the volumes at various temperatures calculated from this expression. Column III. gives the free space at various temperatures, assuming  $b$  to be constant, e.g.,  $v - b$  at  $120^\circ$  is

$$0.0940 + 0.1670 = 0.2610$$

In column IV.,  $v - b$ , is calculated from the equation

$$\pi = \pi_0 e^{c'/Tv} = \frac{RT}{v - b}$$

$$\text{or} \quad v - b = \frac{B'T}{e^{c'/T_0}}$$

$$\text{where} \quad B' = \frac{R}{\pi_0} = 0.001677$$

$$\text{and} \quad c' = 428.5.$$

TABLE I.

I. Temp. $^\circ\text{C.}$	II. Vol.	III. ( $v - b$ ) <sub>obs.</sub>	IV. ( $v - b$ ) <sub>calc.</sub>
0	1.0000	0.0940	0.0953
10	1.0119	0.1059	0.1063
20	1.0238	0.1178	0.1178
30	1.0360	0.1300	0.1298
40	1.0485	0.1425	0.1424
50	1.0612	0.1552	0.1553
60	1.0745	0.1685	0.1683
70	1.0882	0.1822	0.1824
80	1.1025	0.1965	0.1969
90	1.1174	0.2114	0.2118
100	1.1331	0.2271	0.2271
110	1.1496	0.2436	0.2430
120	1.1670	0.2610	0.2592

As  $b$  has been considered a constant, which is probably true only to a first approximation, the agreement is satisfactory.

### The Effective Molecular Weight in a Liquid.

The view has been taken that a certain number of molecules tend, under the ordinary van der Waals' forces, to combine momentarily. These molecules would increase the average effective molecular weight. The forces which control the number of temporarily combined molecules are the forces which ultimately cause the liquid to solidify. Combination of this sort will, therefore, occur in all liquids. If in addition to the ordinary van der Waals' forces, there are also polar forces present, association will be of a more extensive and permanent nature. The van der Waals' forces in most liquids being very similar, it would be impossible to detect this type of association by many physical methods, because it is the normal and inevitable condition of a liquid. The divergences of liquids, however, from generalised laws are probably due to varying degrees of association.

As with the internal pressure, we should expect the effective molecular weight to be equal to the true molecular weight multiplied by an exponential term, following Maxwell's law, or if  $M_0$  is the true molecular weight, the effective molecular weight should be  $M_0 e^{c''/T^0}$ , where  $c''$  is a constant. In spite of the above statement, a liquid would act in most physical changes as though its molecular weight were  $M_0$ , because in

<sup>4</sup> *Trans. Roy. Soc., A*, 1894.

any interchange of molecules, those temporarily in association would automatically be excluded. Under great external pressure, the effective molecular weight would be still further increased, accounting in part for the great increase in viscosity of liquids under pressure. In general we would expect  $c''$  to be less than  $c'$ , because two molecules would need to be in much closer association to move as one, than they would need to be to exert an internal cohesion greater than the average.

### The Viscosity of a Liquid.

We now replace the quantity  $M_0\alpha$  in the equation  $\eta = \frac{KM_0\alpha}{v-b}$  by the quantity  $M_0e^{c''/T_0}$  so that

$$\eta = \frac{KM_0e^{c''/T_0}}{v-b} \quad (2)$$

Substituting for  $v-b$ , the quantity  $\frac{RT}{\pi_0 e^{c'/T_0}}$

from equation (1) we have,

$$\begin{aligned} \eta &= \frac{KM_0 \cdot \pi_0 \cdot e^{c'/T_0} \cdot e^{c''/T_0}}{RT} \\ &= \frac{Be^{c'/T_0}}{T} \end{aligned} \quad (3)$$

where

$$B = \frac{KM_0\pi_0}{R} \text{ and } c = c' + c''.$$

This is very similar to Andrade's equation

$$\eta e^{c/T} = Be^{c'/T}$$

and can be shown to give a similar agreement between observed and calculated values.

$$\text{The equation } \eta = \frac{KM_0 \cdot e^{c''/T_0} \cdot \pi_0 e^{c'/T_0}}{RT}$$

means that the viscosity of a liquid is directly proportional to its internal pressure and to the effective molecular weight and inversely proportional to the absolute temperature.

It will be noted that whereas each of the equations  $\eta = \frac{KM_0e^{c''/T_0}}{v-b}$  and  $\pi_0 e^{c'/T_0} = \frac{RT}{v-b}$  contains three unknowns, by eliminating  $v-b$  we get  $\frac{\eta = Be^{c'/T_0}}{T}$  containing two unknowns.

The application of the equation

$$\eta = \frac{KM_0e^{c''/T_0}}{v-b}$$

to octane will now be given. The value of the free space,  $v-b$ , is the same as that used for the change of volume with temperature namely 0.0940.

In Table II., column II., gives the observed values of the viscosity taken from Thorpe and Rodger.<sup>4</sup> Column III. gives the values of the viscosity calculated from equation (2) with  $KM_0 = 0.037$ ,  $c'' = 134.5$

## 876 NOTE ON THE THEORY OF VISCOSITY OF LIQUIDS

and  $v - b = 0.0940$ . It will be seen that the agreement between the observed and calculated values is within the experimental error.

TABLE II.—OCTANE.

110	0.002255	0.002255	0.0
120	0.002075	0.002085	+ 0.5

In applying the equation  $\eta = \frac{Bc^{1/2}v}{T}$  to the same liquid,  $c$  should of course be equal to  $c' + c''$ . A separate solution has been made for each table so that whereas the value taken for  $c$  in Table III. is 565.5,

$$c' + c'' = 428.5 + 134.5 = 563.0$$

The difference, therefore, is very small.

In Table III.  $B = 0.2392$  and  $c = 565.5$ .

Comparison with Andrade's figures for octane (*loc. cit.*, p. 710) shows that the above agreement is similar to that obtained from his equation. Application to other liquids reveals a similar agreement.

As Andrade has discussed extensively the application of an equation of this type it is unnecessary to give further illustrations. The meaning of the constants in both cases must be similar.

I wish to thank Dr. C. Coleridge Faur, F.R.S., for encouragement in this work.

# ON THE DECOMPOSITION OF DIAZO-ACETIC ESTER CATALYSED BY PROTONS AND DEUTONS.

BY PH. GROSS, H. STEINER AND F. KRAUSS.

*Received 13th March, 1936.*

In this paper we record experiments on the decomposition of diazo-acetic ester in mixtures of heavy and light water when catalysed by protons and deutons, which were carried out in order to gain a better insight into the mechanism of such reactions. They form part of our investigation into the connection between kinetics and thermodynamics in such mixtures reported in the succeeding two papers.

The decomposition of diazo-acetic ester is well suited for such purposes both for experimental and theoretical reasons. Firstly, the measurement of the reaction rate can be carried out easily on a micro-scale by determining the volume of nitrogen produced in the course of the reaction  $\text{N}_2\text{CH}-\text{COOC}_2\text{H}_5 + \text{H}_2\text{O} = \text{HOCH}_2-\text{COOC}_2\text{H}_5 + \text{N}_2$ . Secondly, this reaction cannot, so far as we know, be taken as an example of generalised acid catalysis.<sup>1</sup> In order to avoid complications we used picric acid to acidify the solutions.

## I. Experimental.

### (a) Materials.

The ester used was purified<sup>2</sup> and redistilled in vacuo several times. The solutions of picric acid (Merck p.a.) were prepared by mixing measured amounts of a standard solution of picric acid in  $\text{D}_2\text{O}$  with measured amounts of a 0.01 *N* aqueous ( $\text{H}_2\text{O}$ ) solution of picric acid. The standard solution in  $\text{D}_2\text{O}$  was prepared by weighing out picric acid into  $\text{D}_2\text{O}$ , using a micro-balance. The acidity and the total amount of deuterium present in the mixtures were computed from the concentrations and amounts of the constituents.

### (b) Apparatus and Experimental Procedure.

The reaction vessel \* was a bulb of about 1 c.c. capacity attached to the other parts of the apparatus by two ground joints. To avoid supersaturation a stream of the air present in the apparatus could be circulated through the solution. Preliminary experiments in a Jena glass vessel yielded values markedly lower than that extrapolated for 0° C. from values ascertained in older macroscopic measurements. With a vessel of quartz-glass these differences almost disappeared. The lower reaction rate with the glass vessel may have been due to adsorption of part of the picric acid at the glass surface.

The volume of the nitrogen evolved was measured at constant pressure.

<sup>1</sup> J. N. Brönsted, *Chem. Rev.*, 1928, 5, 251.

<sup>2</sup> W. Fraenkel, *Z. physik. Chem.*, 1907, 60, 202.

\* A more detailed description of the apparatus used in these experiments will be given later in *Mikrochemie*.

In each experiment there was placed in the reaction vessel first 5 c.mm. of ester and then 0.37 c.c. of picric acid solution, which corresponds to a dilution of the ester to 1.3 per cent. strength. As thermostat we employed a Dewar flask with ice water agitated by a current of air.

After six to ten readings had been made the reaction vessel was immersed in water at a temperature of 30–40° C., for the purpose of completely decomposing the ester. After the lapse of half an hour the final volume was read off with the reaction vessel in an ice bath.

## II. Results.

The values of  $\ln \frac{a}{a-y}$  were plotted as a function of the time  $t$ ,  $y$  denoting the reading at time  $t$ ,  $a$  the initial reading. The points fit very well to a straight line. The velocity constants were obtained by dividing the slope of these lines by the picric acid concentration. In Table I. all the values obtained are given:—

energy of the D substrate bond; but one has to expect that the activation does not take place in this bond otherwise the two effects would cancel each other. In both the two hitherto known cases the rates of reaction are about doubled, so that the increase found in the present instance represents the highest yet known. In this connection we want to emphasise that in the present case, as already mentioned, most certainly no generalised acid catalysis occurs. In the light of thermodynamic considerations suggested by this investigation and that of cane sugar inversion a somewhat more detailed analysis is given later.\*

\* This number, Gross, Steiner and Suess, p. 883.

The hydrolysis of diazo-acetic ester thus proceeds in pure heavy water roughly three times as rapidly as in pure light water, the increase in rate being not linear. The increase in the rate of such hydrolytic reactions in heavy water is known<sup>3</sup> and has already been discussed.<sup>4</sup> It has been attributed to an increase in the concentration of a reacting complex consisting of substrate and either H or D ion. This increase is due to the smaller zero point

### Summary.

The decomposition rate of diazo-acetic ester in mixtures of light and heavy water catalysed by H and D ions at 0° C. increases with the D content of the solvent and is in pure heavy water about three times as high as in pure light water. The increase is far from being a linear function of the analytical D content.

## ON THE DISTRIBUTION OF PICRIC ACID BETWEEN BENZENE AND MIXTURES OF LIGHT AND HEAVY WATER.

BY PH. GROSS AND A. WISCHIN.

*Received 13th March, 1936.*

In order to investigate whether inherent relations exist between the rate of reactions in water with changing D<sub>2</sub>O content and the conditions governing the equilibrium in such mixtures we measured the distribution of picric acid between water of various compositions and benzene. Picric acid is especially well suited for the purposes of this investigation, as in dilute aqueous solutions the partition ratio does not differ much from unity and the acid can be taken as being perfectly dissociated.

### I. Experimental.

#### (a) Materials.

The picric acid was recrystallised several times and had been proved to be optically pure in previous occasions.<sup>1</sup> The benzene was free from thiophene and washed with alkaline solution and with water. One part of the deuterium oxide was prepared by electrolysis and then redistilled in a high vacuum, the rest was a commercial product of neutral reaction against phenolphthalein. Conductivity water was used for control experiments in pure light water.

#### (b) Method of Analysis.

For all our experiments we prepared a 0.02979 molal standard solution by weighing out picric acid into benzene. The concentration was checked several times. The concentration of the approximately *N*/10 alkali solution was determined by titration with aqueous solutions of picric acid prepared by direct weighing. As indicator we used phenolphthalein and a standard solution as a basis for colour comparison. By carrying out the titrations in the actual experiments in the same manner, minor systematic errors due possibly to the fact that not quite the right colour was taken as end-point and that the amount of carbon dioxide present in the solution was disregarded are cancelled. For measuring the volume of the solutions, carefully calibrated micro-pipettes of 1 c.c. and 0.5 c.c. capacity were used and for titration a micro-burette<sup>2</sup> of 200 c.mm. capacity permitting readings to within 0.5 c.mm.

<sup>1</sup> Ph. Gross, A. Jamöck and F. Patat, *Sitz. Ber. Akad. Wiss., Wien, IIb*, 1933, 142, 327; *Monatsh. Chem.*, 1933, 63, 117.

<sup>2</sup> K. Schwarz, *Mikrochemie*, 1933, 13, 1, and 1935, 18, 309.

The  $D_2O$  percentage of the water was determined by density measurements, using the above described 1 c.c. pipette as a pycnometer, invariably filled, in a thermostat at 18° C.

### (c) Experimental Procedure.

All experiments were carried out in a thermostat at  $18.00 \pm 0.005^\circ$  C. One c.c. of water was shaken with 1 c.c. of the standard solution of picric acid in benzene in a sealed-up tube of Jena glass for half an hour. After the two layers had been allowed to separate and become clear for again half an hour 0.5 c.c. of each of the phases were withdrawn with the pipette and titrated.

## II. Results.

The results of the measurements are given in Table II. The total amount of picric acid should naturally equal the sum of the amounts found in both phases. The sum found is given in Table II. column  $\Sigma$ . The differ-

\* Average value.

† Extrapolated.

$D_{18}^{18}$  = Density at 18° C. referred to water at 18° C.

$x$  = Analytical mole fraction of  $D_2O$ .

$c_b$  = Concentration of picric acid in the benzene phase in mole/litre.

$c_w$  = Concentration of picric acid in the aqueous phase in mole/litre.

$\Sigma$  = Sum of the amount of picric acid found in both phases.

$K$  = Thermodynamic distribution constant =  $\frac{c_b}{c_w \cdot \gamma^2}$ .

$\gamma$  = Interionic activity coefficient.

$\eta(x)$  = Ratio of  $K$  to the respective constant for pure light water.

ence between the amount of picric acid actually used (in all cases 0.02963) and the values of  $\Sigma$  averages about 1.8 per cent. The thermodynamic constant of distribution was computed from the concentration of picric acid in water ( $c_w$ ) and in benzene ( $c_b$ ) with the help of the activity coefficient of picric acid determined with the aid of the well-known Debye-Hückel formula. According to this formula we have at 18° C.:  $\log \gamma^2 = \sqrt{c_w}$ . The value given in the table for pure light water is a mean value of 10 independent measurements all carried out on a micro scale. The average error in any single measurement was 1.4 per cent. The difference between the value obtained in these blank experiments and that calculated <sup>7</sup>

<sup>7</sup> Ph. Gross and O. Halpern, *Physik. Z.*, 1924, 25, 393.

from the results of the experiments made by Rothmund and Drucker<sup>8</sup> (showing an error of 1.4 per cent. in  $K$  and of 0.6 per cent. in  $\Sigma$ ) is about 4.3 per cent. In our opinion this minor difference is systematic and may perhaps be due to the fact that our experiments were carried out on a micro-scale. It should be noted that all the  $\Sigma$  values are greater than the amount of picric acid actually used and that these differences are of the same order of magnitude as the differences between the present value and the value found by Rothmund and Drucker. Therefore the ratio  $K/K_0$  may have a small error.

### III. Discussion and Theory.

The change which the distribution of picric acid undergoes when pure heavy water is substituted for pure light water as solvent, is attributable to a change in dissociation energy. This change is due to the fact that the zero point energy of the H- and D-linkage in the initial and end states of the reactions

differ from each other. We believe it to be a justifiable assumption that the solubility of the undissociated molecules does not change. This diminution of the dissociation constant has been observed already in the case of water and of acetic acid and is to be expected in view of Halpern's theoretical treatment<sup>9</sup> of this question in all cases in which the dissociation constant (when expressed in moles/litre) is less than approximately the number of water molecules in a litre.

The following treatment will be an aid to understanding the dependence of the distribution coefficient on the composition of water.

If  $h$  and  $d$  denote the activities of protons and deuterons respectively, we have, according to the reaction  $2\text{H}^+ + \text{D}_2\text{O} = 2\text{D}^+ + \text{H}_2\text{O}$ :

$$\frac{h}{d} = \frac{1}{q} \sqrt{\frac{a_{\text{H}_2\text{O}}}{a_{\text{D}_2\text{O}}}} \quad (1.1)$$

In this  $a_{\text{H}_2\text{O}}$  and  $a_{\text{D}_2\text{O}}$  denote the activities of  $\text{H}_2\text{O}$  and  $\text{D}_2\text{O}$  respectively, and  $q$  is a constant. We now limit ourselves to solutions which are so dilute that the mole fraction of the water molecules linked to H- or D-ions ( $\text{H}_3\text{O}^+$ ,  $\text{H}_2\text{DO}^+$ ,  $\text{HD}_2\text{O}^+$ ,  $\text{D}_3\text{O}^+$ ) is small compared with the mole fraction of the corresponding free water molecules ( $\text{H}_2\text{O}$ ,  $\text{HDO}$ ,  $\text{D}_2\text{O}$ ). Then the proton activity is nothing but the product of the following two factors: (a) picric ion activity and (b) a function of the  $\text{D}_2\text{O}$  content. The activity of picric ions equals the product of the analytical concentration of picric acid  $P$  and the interionic activity coefficient  $\gamma$ , because the acid can be regarded as perfectly dissociated. Thus

$$h = P \cdot \frac{1}{Q(x)} \cdot \phi(x) \cdot \gamma \quad (1.2)$$

and similarly

$$d = P \cdot \frac{q}{Q(x)} \cdot \psi(x) \cdot \gamma \quad (1.3)$$

if  $x$  denotes the analytical mole fraction of  $\text{D}_2\text{O}$ , and  $\phi(x)$ ,  $\psi(x)$  and  $Q(x)$  denote different functions of  $x$ . A comparison of (1.2) and (1.3) with

<sup>8</sup> V. Rothmund and C. Drucker, *Z. physik. Chem.*, 1903, **46**, 827.

<sup>9</sup> O. Halpern, *J. Chem. Physics.*, 1935, **3**, 450.

(1.1) shows that  $\phi(x)$  is proportional to the square root of the  $H_2O$  activity,  $\psi(x)$  is proportional to the square root of the  $D_2O$  activity. The proportion constant is taken to be unity. According to the usual practice we define the proton activity in pure light water at the reference temperature as  $h = P \cdot \gamma$ , and similarly the deutron activity in pure heavy water as  $d = P \cdot \gamma$ . Then we have

$$\begin{aligned} Q(0) &= 1. & \phi(0) &= 1. \\ Q(1) &= q. & \psi(1) &= 1. \end{aligned}$$

The value of the equilibrium constant

$$L = \frac{a_{HDO}^2}{a_{H_2O} \cdot a_{D_2O}} \quad . \quad . \quad . \quad . \quad (2)$$

is essentially dependent on the difference between the zero point energies.<sup>10</sup> The heat of reaction experimentally found<sup>11</sup> gives a value of  $L = 3.97$ . If we therefore assume that  $L$  is about 4 and furthermore that the association of the water molecules does not change the equilibrium we can take the activities to be identical with the mole fractions of the individual types of water molecules. Thus

$$a_{H_2O} = (1 - x)^2, \quad . \quad . \quad . \quad . \quad (3.1)$$

$$a_{HDO} = 2x(1 - x), \quad . \quad . \quad . \quad . \quad (3.2)$$

$$a_{D_2O} = x^2. \quad . \quad . \quad . \quad . \quad (3.3)$$

Thus we have instead of (1.1), (1.2) and (1.3):

$$\frac{h}{d} = \frac{1}{q} \cdot \frac{1 - x}{x}, \quad . \quad . \quad . \quad . \quad (1.1')$$

$$h = P \cdot \frac{1}{Q(x)} \cdot (1 - x) \cdot \gamma, \quad . \quad . \quad . \quad . \quad (1.2')$$

$$d = P \cdot \frac{q}{Q(x)} \cdot x \cdot \gamma. \quad . \quad . \quad . \quad . \quad (1.3')$$

For the distribution of picric acid between benzene and pure light water the following relation holds:

$$h \cdot P \cdot \gamma = \frac{c_l}{K_l} \quad . \quad . \quad . \quad . \quad (4.1)$$

and similarly for pure heavy water:

$$d \cdot P \cdot \gamma = \frac{c_h}{K_h}. \quad . \quad . \quad . \quad . \quad (4.2)$$

Here  $K_l$  and  $K_h$  denote the distribution constants of picric acid between benzene and pure light or pure heavy water respectively,  $c_l$  and  $c_h$  the concentration of light and heavy picric acid, respectively, in benzene. From (4.1) and (4.2) we obtain the dependency of the distribution constant on the composition of the water. The ratio of this constant to the constant in pure light water is therefore

$$\eta(x) = \frac{c_b}{\gamma^2 P^2 K_l} = \frac{1}{Q(x)} [1 - x(1 - q \cdot \eta(1))]; \quad c_b = c_l + c_h. \quad (5)$$

<sup>10</sup> B. Topley and H. Eyring, *J. Chem. Physics*, 1934, **2**, 217.

<sup>11</sup> E. Doehlemann and E. Lange, *Z. Elektrochem.*, 1935, **41**, 539.

The value of  $q$  can be computed from <sup>12</sup>

$$q = \frac{1}{M} \sqrt{\frac{L}{N}} \exp. \frac{(\epsilon_H - \epsilon_D)F}{RT},$$

therein  $M = \frac{[H_2] \cdot a_{HDO}}{[HD] \cdot a_{H_2O}} = 3.04$  and  $N = \frac{[HD]^2}{[H_2][D_2]} = 3.26$  denote

equilibrium constants and  $\epsilon_H - \epsilon_D = 3.4 \times 10^{-3}$  Volt, the normal potential difference,<sup>13</sup> the numerical values holding at room temperature (21° C.). Not even a considerable error in this difference would change the value of  $q$  appreciably.

We calculated a series of points of the function  $Q(x)$  governing the equilibrium of the different water ions from our distribution measurements for the corresponding values of  $x$  with the help of the above given value of  $q$  and plotted them against  $x$  in a graph reproduced in the next paper (Gross, Steiner and Suess (p. 886), where there also is given another method of calculating the function  $Q(x)$ ). For this reason and for the sake of brevity a more detailed combined discussion has been reserved for this later paper.

### Summary.

The distribution of picric acid between benzene and mixtures of light and heavy water at 18° C. has been measured. The distribution coefficient increases with the D<sub>2</sub>O content but not linearly. The value of the distribution constant in pure heavy water is about four times as great as in pure light water. This effect is due to the differences between the zero point energies in the various D- and H-linkages. The dependence of the distribution constant on the composition of the water is treated from the standpoint of thermodynamics.

## THE INVERSION OF CANE SUGAR IN MIXTURES OF LIGHT AND HEAVY WATER.

BY PH. GROSS, H. STEINER AND H. SUESS.

*Received 13th March, 1936.*

This paper deals with cane sugar inversion in mixtures of light and heavy water. After an account of the experiments made we pass on to an attempt to carry out as general as possible an analysis of the equilibria in which the ions of "water" participate. On the strength of this analysis it becomes possible, in conjunction with the experiments carried out, to draw conclusions as to the mechanism of reactions catalysed by hydrogen ions.

## I. Experimental.

All solutions were prepared in the following manner: To 0.2 g. of water, the isotopic composition of which was determined by density measurement, we added, with the aid of a micro-pipette, a measured amount of approximately 7 *N* sulphuric acid of known concentration. To the approximately 0.3 *N* sulphuric acid thus obtained we added an accurately weighed out quantity of cane sugar (approximately 10 per cent. by weight). In experiment 6 we employed the corresponding quantity of titrated concentrated sulphuric acid instead of the 7 *N* acid. In ascertaining the total D content, allowance was made for the dilution due to the addition of sulphuric acid and sugar. For measurement of the optical rotation we employed a polarimeter capable of reading to within 0.01° and a micro-tube of 5 cm. length and 1 mm. diameter. The source of light was a sodium discharge lamp of high brilliancy. Each polarimeter reading represents the average of three independent settings. The experiments were carried out in a thermostat at  $25 \pm 0.05^\circ \text{C}$ ., the micro-polarimeter tube being removed just for the short time of readings. As the tube was not equipped with a jacket the room was heated to  $25^\circ \text{C}$ . At the start, readings were taken every 20 minutes and were continued until no alteration in the rotation could be detected for several hours on end. From the last of the values obtained we deduced the initial concentration.

The constants were obtained in the usual graphical manner, the single points fitting very well to a straight line.

## II. Results.

Table III. gives the results of all experiments and the values for pure heavy water extrapolated therefrom.

TABLE III.—THE INVERSION RATE OF CANE SUGAR AT  $25^\circ \text{C}$ . AS A FUNCTION OF THE  $\text{D}_2\text{O}$  CONTENT OF THE SOLVENT WATER.

† Average value.

‡ Extrapolated.

$x$  = Analytic mole fraction of  $\text{D}_2\text{O}$ .

$P$  = Analytic concentration of sulphuric acid in aequiv./litre.

$$\zeta(x) = \frac{\frac{dS}{dt} \cdot K_1'}{P \cdot S \cdot k_1'}$$

If the values for  $\frac{1}{\zeta(x)}$  be plotted against  $x$  they will be found to lie on a continuous curve the form of which permits extrapolation of the value  $\zeta(1) = 2.05$  for pure heavy water without danger of a serious error. Between this value and that arrived at by Moelwyn-Hughes<sup>14</sup> there is a difference which is obviously greater than the respective experimental

<sup>14</sup> E. A. Moelwyn-Hughes, *Z. physik. Chem.*, 1934, **26B**, 278.

errors. As yet we have had no opportunity of going into the question of this discrepancy. It may possibly be due to the difference in concentration between the catalysts used.

### III. Theoretical Discussion.

#### (a) Preliminary Remarks.

The alteration in the rate of reactions catalysed by hydrogen ions on passing from light to heavy water as solvent has been attributed to the difference between the concentrations of the reacting complex. This complex consists of the substrate to which there is linked in the one case an H ion, in the other case a D ion. Proceeding from this assumption, the dependence of the reaction rate on the  $D_2O$  content of the solvent is completely described by the thermodynamic conditions, provided the following pre-suppositions are in accordance with fact:

1. That the decomposition constant is unaffected by the medium, *i.e.*, that the reaction with the water takes place, either after each activation in the narrower sense, or just as readily with  $H_2O$  as with  $D_2O$  (the contribution of the zero point energy of the water molecule non-existent or negligible or cancelled).

2. That the concentration of the complex is invariably the equilibrium concentration, *i.e.* the rate of formation of the complex is great in comparison with the reaction rate.

Assuming these pre-suppositions to be justified the following equation holds for the reaction rate:

$$-\frac{dS}{dt} = k_l \frac{h \cdot S}{\gamma \cdot K_l'} + k_h \frac{d \cdot S}{\gamma \cdot K_h'} \quad (6)$$

We now use the same notation as before:  $h$  and  $d$  for the activities of proton and deuteron respectively,  $\gamma$  for the interionic activity coefficient. In addition  $k_l$  and  $k_h$  stand for the reaction constants in pure light and pure heavy water, and  $K_l'$  and  $K_h'$  for the dissociation constants of the reacting complex;  $S$  denotes the concentration of the substrate. From this equation we obtain (with the help<sup>15</sup> of equations (1.2') and (1.3')) for the ratio between the reaction constant for any desired composition of water and the reaction constant for pure light water:

$$\zeta(x) = \frac{\frac{ds}{dt} \cdot K_l'}{P \cdot S \cdot k} = \frac{1}{Q(x)} \cdot 1 - x(1 - q \cdot \zeta(1)) \quad \zeta(1) = \frac{k_h}{k_l} \cdot \frac{K_l'}{K_h'} \quad (7)$$

In perfect analogy with the thermodynamics of picric acid distribution the function  $Q(x)$  can be computed from the function  $\zeta(x)$ . We calculated the values for the function  $Q(x)$  on the one hand from the ascertained values for picric acid distribution, and on the other hand from measurements of the reaction rates of diazo-acetic ester decomposition and of cane sugar inversion, and plotted them in the diagram (Fig. 1) against the  $D_2O$  content of the solvent. All the experiments ought of course to have been carried out at the same temperature. Since this, however, was not possible for experimental reasons, the temperature differences are for the time being neglected on the assumption that the temperature coefficients of the constants concerned are so small that

<sup>15</sup> We refer to equations of the preceding paper by number only.

the deviation within the range of temperature involved is of subsidiary significance.

It will be seen that the course of the function  $Q(x)$  obtained in the case of the decomposition of diazo-acetic ester is the same as that obtained in the case of picric acid distribution. This agreement is hardly affected by the numerical value of the constant  $q$ . We conclude from this agreement that, in the case of the ester decomposition, the above-mentioned pre-suppositions are very fairly true so that the analogy emphasised by Halpern<sup>16</sup> is indeed perfect.

The same agreement would of course follow from the assumption of a bimolecular collision mechanism in which the reaction rate constants

FIG. 1.

are inverse proportional to the equilibrium constants. This, however, is hardly probable<sup>17</sup> and merely *ad hoc*.

### (b) Calculation of the Ionic Equilibria in Water.

Before discussing the deviations occurring in cane sugar inversion we will give a more detailed statement of the physical significance of the function  $Q(x)$ , the more general bearing of which proceeds clearly from the agreement found in the two cases just mentioned. For this purpose it is assumed that the ions  $H_3O^+$ ,  $H_2DO^+$ ,  $HD_2O^+$  and  $D_3O^+$  are actually present.

Then, on the truly very general assumptions made in the preceding paper, the most general form of the equilibrium conditions is :

<sup>16</sup> O. Halpern, *J. Chem. Physics.*, 1935, **3**, 456.

<sup>17</sup> See J. N. Brønsted, *Chem. Rev.*, 1928, **5**, 318.

$$\frac{[H_2O'] \cdot \gamma}{h \cdot a_{H_2O}} = 1 \quad (8.1) \quad \frac{[D_2O'] \cdot \gamma}{d \cdot a_{D_2O}} = 1 \quad (9.1)$$

$$\frac{[H_2DO'] \cdot \gamma}{h \cdot a_{HDO}} = \frac{3}{2} r_2 \quad (8.2) \quad \frac{[HD_2O'] \cdot \gamma}{d \cdot a_{HDO}} = \frac{3}{2} s_2 \quad (9.2)$$

$$\frac{[HD_2O'] \cdot \gamma}{h \cdot a_{D_2O}} = 3 r_1 \quad (8.3) \quad \frac{[H_2DO'] \cdot \gamma}{d \cdot a_{H_2O}} = 3 s_1 \quad (9.3)$$

and

$$\frac{h \cdot oh}{a_{H_2O}} = k_{11} \quad (10.1) \quad \frac{d \cdot oh}{a_{HDO}} = k_{21} = \frac{k_{11}}{2} \frac{r_2}{s_1} \quad (10.3)$$

$$\frac{h \cdot od}{a_{HDO}} = k_{12} = \frac{k_{22}}{2} \frac{s_2}{r_1} \quad (10.2) \quad \frac{d \cdot od}{a_{D_2O}} = k_{22} \quad (10.4)$$

if we denote the mole fractions by the respective chemical symbols in brackets, the activities of the hydroxyl ions by  $oh$  and  $od$ , and if the  $r$ ,  $s$  and  $k$  are constants.

In this connexion the same assumption is made as to the units of the activities as was made in the previous paper, which of course does not detract from the universal character of these equations.

By comparing (9.3)/(8.2) and (9.2)/(8.3) with (1.1) and (2) we find

$$q = \frac{2}{\sqrt{L}} \cdot \frac{r_2}{s_1} = \frac{\sqrt{L}}{2} \cdot \frac{r_1}{s_2}$$

And if we assume

$$L = 4 \quad (11.1)$$

it follows that

$$q = \frac{r_2}{s_1} = \frac{r_1}{s_2} \quad (11.2)$$

Since account has been taken of the statistical weights by introducing the numerical factors<sup>18</sup> it would appear obvious to assume that the constants  $r$  and  $s$  are equal to unity. This, however, would lead to consequences in contradiction with facts, as, e.g., a glance at (11.2) shows. On this assumption the cane sugar inversion also would be linearly dependent on concentration. The deviations from the linear and considerations connected with this train of thought (see equations 10) led us to conclude that the dissociation constants of heavy and light water are unequal.<sup>19</sup> The assumption  $r = s = 1$  is therefore mistaken. It is only admissible to assume that the constants  $r$  and  $s$  are of the order of magnitude of unity.

Proceeding from the condition of electro-neutrality we get with the aid of the equations (1.1'), (1.2'), (3.1) – (3.3), (8.1) – (8.3) and (9.1)

$$Q(x) = 1 - 3x(1 - r_2) + 3x^2(1 - 2r_2 + r_1) - x^3 \left( 1 - 3r_2 + 3r_1 - \frac{r_2}{s_1} \right) \quad (12)$$

If we choose  $r_1 = 0.50$  and  $r_2 = 0.64$  we obtain the curve which is shown in Fig. 1 as a thick line and which fits best the ascertained values. For  $s_1$  and  $s_2$  we thus obtain with the help of  $q = 0.317$  the values  $s_1 = 2.02$  and  $s_2 = 1.59$ .

It would naturally appear desirable to obtain, in addition to purely experimental data, theoretical indications for determining the constants,

<sup>18</sup> R. Wegscheider, *Monatsh f. Chem.*, 1895, 16, 153.

<sup>19</sup> See Ph. Gross, H. Süss and H. Steiner, *Naturwiss.*, 1934, 22, 662.

especially seeing that the experimental determination of the constants  $r$  is based on measurements carried out on a micro-scale and therefore not very accurate. The most plausible assumption for this purpose, having regard only to the different symmetries of the ions  $H_3O^+$ ,  $H_2DO^+$  and  $HD_2O^+$ , would be that  $r_2 = \sqrt{r_1}$  and  $s_2 = \sqrt{s_1}$ . This assumption simplifies the function  $Q(x)$  to

$$Q(x) = [1 - x(1 - \sqrt{r_1})]^3 \quad \sqrt{r_1} = \sqrt[3]{q}.$$

The curve representing this function is shown as a thin line in Fig. 1. It will be seen that the two curves do not differ much one from the other.

### (c) On the Mechanism of the Inversion of Cane Sugar and Similar Reactions.

In the case of cane sugar inversion there occur systematic deviations which are small but obviously outside the limits of experimental error. These may be due to the fact that we used sulphuric acid as catalyst and regarded it as being completely dissociated. If this brings about too great an error the change in the degree of dissociation of  $HSO_4^-$  ions with changing  $D_2O$  content should have been allowed for. Since the value of (1) has been found<sup>14</sup> to be independent of the catalysing acid ( $DCl$  or  $D_2SO_4$ ), albeit with a smaller concentration, it seems that this effect is not of great influence.

Further, it might be assumed that we are here concerned with a quantum mechanical resonance effect, similar to that in the case of the conductivity of hydrogen ions in mixtures of heavy and light water, which effect would be at its weakest in mixtures of approximately equal parts.\* This possibility cannot, it is true, be precluded with certainty, but we are not entitled to draw any conclusions in favour of such an effect from the mere fact that the ascertained values deviate most markedly just in mixtures of equal parts, since, by definition, there must be agreement in the endpoints.

Finally we have to discuss the consequences when one of the above mentioned pre-suppositions is not justified. This discussion is of more general theoretical importance.

If the calculation is carried out on the assumption that the true activation energy of the reacting partners is different owing to the difference of the zero point energies, the function  $Q(x)$  will be found to be

$$Q(x) = \frac{1}{(x)} [1 - x(1 - q \cdot (1))] \cdot [1 - x(1 \pm b)] \quad (14)$$

$b$  denoting the relative difference between the true velocity constants. If one inserts for  $b$  a value of the order of magnitude of that found experimentally in the case of enzymatic cane sugar inversion,<sup>20</sup> i.e.  $\pm 1/4$  the deviations remain systematic and approximately of the same magnitude as before.

\* This is actually the fact in the case of H and D ion mobility. The conductivity of a strong acid is not a linear function of the  $D_2O$  content. If the relative deviations from the straight line passing through the end points be plotted against the  $D_2O$  content in accordance with the experiments carried out by W. N. Baker and V. K. la Mer (*J. Chem. Physics.*, 1935, 3, 406) (at 26° C.) a nearly parabolic curve results with the maximum at about  $x = 0.5$ . If the same is done in accordance with our own experiments (*Sitzber. Akad. Wiss., Wien*, 11 b, 1935, 144, 243; *Monatsh. Chem.*, 1935, 66, 111) carried out on a micro scale and at a different temperature (18° C.) practically the same curve is obtained.

<sup>20</sup> E. W. R. Steacie, *Z. physik. Chem. (B)*, 1934, 27, 6.

If the other pre-supposition is not in accordance with fact *the concentration of the complex actually obtaining is not invariably the equilibrium concentration, and the reaction rate is therefore not governed by the equilibrium concentration. This will be the case if generalised acid catalysis occurs.*<sup>21</sup> Moreover agreement with thermodynamics is not to be expected in the second case treated by Halpern.<sup>16</sup> In this case the complex concerned (the concentration of which is very small), behaves like an extremely strong acid. What would be expected is generalised acid catalysis, the formation of the complex being the rate determining step. A lessening of the reaction rate has, indeed, been found in the case of mutarotation of glucose<sup>22</sup> which is a thoroughly investigated example of generalised acid catalysis.<sup>23</sup>

An indication that in the special case of cane sugar inversion, generalised acid catalysis also plays a part, and that therefore the second pre-supposition is not quite justified, is supplied by experiments of Hantzsch and Weissberger<sup>24</sup> which have been discussed by Hammet and Paul.<sup>25</sup>

In any event, the deviations are of minor importance and the experiments corroborate the view that the increase in reaction rate is due to an increase in the concentration of the reacting complex, and that on this effect there is superposed a further effect which may possibly be closely connected with other irregularities met with in cane sugar inversion.<sup>26</sup>

### Summary.

The inversion rate of cane sugar in mixtures of light and heavy water at 25° C. was measured and was found to increase with the D<sub>2</sub>O content, but not linearly. The increase in rate of this reaction and of the decomposition of diazo-acetic ester is attributed to an increase in concentration of the reacting complexes. A quantity proportional to the concentration of the complex can be computed according to a thermodynamic formula which is given and discussed. The decomposition of diazo-acetic ester is in complete agreement with the theory given. In the case of cane sugar inversion, there appear deviations which are small but obviously systematic, their possible causes are discussed. The relations between generalised acid catalysis and proton catalysis and the decrease and increase of the rate of protolytic reactions in heavy water, respectively, are discussed.

One of the authors (Ph. G.) is very much indebted to the Van't Hoff Fonds for a financial grant from which the cost of carrying out these investigations was in part defrayed.

We are also very much indebted to Miss K. Schiff, D.Phil., for her valuable assistance in discussing and preparing these papers.

# THE SURFACE COMPOSITION OF THE RUBBER GLOBULES IN HEVEA LATEX.

BY I. KEMP AND D. F. TWISS.

*Received 16th March, 1936.*

The latex of *Hevea brasiliensis* consists of rubber globules suspended in a serum containing proteins, rubber "resin" (*i.e.* acetone-soluble substances) and methylinositol, together with smaller quantities of sugars and saline substances. The so-called "resin" of rubber has been shown by Whitby, Dolid and Yorston<sup>1</sup> to consist mainly of unsaturated fatty acids together with other fatty acids and sterols. As mentioned later the protein and fatty acids possibly may be partly in some form of association.

The colloidal properties of the latex will depend largely upon the amounts of the capillary-active substances (*i.e.* mainly proteins and "resin") adsorbed at the surface of the rubber globules. The influence of the protein on the behaviour of latex appears first to have been recognised by Weber.<sup>2</sup> Although Weber made his investigations with Castilleja latex and, contrary to present ideas, regarded the rubber in the latex globules as incompletely polymerised, his views on the existence of a surface film of protein steadily received wider acceptance, and it was early realised that they would apply also to the case of *Hevea* latex (which to-day is of paramount importance) although not to all natural latices generally.

This extension of the original observations was clearly stated by de Vries.<sup>3</sup>

The rubber "resin" on the other hand, judging by the experiments of Freundlich and Hauser,<sup>4</sup> of Scholz,<sup>5</sup> and of de Vries and Beumée-Nieuwland<sup>6</sup> has little influence on the stability or behaviour of *Hevea* latex. Subsequently, however, Beumée-Nieuwland<sup>7</sup> has postulated the presence of an adsorbed lipid layer in addition to the adsorbed protein. This theory has been further elaborated by Belgrave<sup>8</sup> and van Rossem<sup>9</sup> who assume the adsorption of a lipid-protein complex.

The recent rapid extension of latex-processes for rubber manufacture involving the need for initial stabilisation of *Hevea* latex and later adjustment of its stability to various degrees as necessary for different methods of use renders desirable as exact knowledge as possible of the character of the active protective substances in commercial latex.

<sup>9</sup> Van Rossem, *Colloid Chemistry*, by J. Alexander (Chemical Catalog. Co.), Vol. IV., 235 (1932).

The object of this paper is to describe the experimental determination of the fractions of the exposed surface of the rubber globule composed of protein and rubber "resin." The method employed is based upon the assumption that the resultant surface-charge density of a composite colloidal particle depends upon the surface-charge densities of the capillary-active substances adsorbed at the particle surface, and upon the fractions of the surface area occupied by those substances. In the case of the globules in Hevea latex, the rubber hydrocarbon surface is more or less occupied by a covering of protein or fatty-acid character. Thus if  $f_p$ ,  $f_F$  be the fractions of the surface covered with protein and with "rubber-resin" respectively,  $f_R$  be the fraction of uncovered rubber surface, and  $\sigma_p$ ,  $\sigma_F$ ,  $\sigma_R$  be the surface-charge densities of the protein, "resin" and rubber surfaces respectively, then it is assumed that the resultant surface-charge density of the latex globule will be

$$\sigma = \sigma_p f_p + \sigma_F f_F + \sigma_R f_R \quad . \quad . \quad . \quad (1)$$

$$\text{or,} \quad \sigma - \sigma_R = (\sigma_p - \sigma_R) f_p + (\sigma_F - \sigma_R) f_F \quad . \quad . \quad . \quad (2)$$

It has previously been shown (Kemp<sup>10</sup>) that the relation between the cataphoretic mobility of a particle and its surface-charge density can be satisfactorily expressed by the equation of Henry,<sup>11</sup>

$$u = \frac{\sigma}{\eta} \cdot \frac{\kappa a}{1 + \kappa a} f(\kappa a) \quad . \quad . \quad . \quad (3)$$

where  $u$  denotes the cataphoretic mobility,  $\sigma$  the surface-charge density,  $\eta$  the coefficient of viscosity of the solution,  $a$  the radius of the particle,  $\kappa$  is proportional to the square root of the ionic strength, and  $f(\kappa a)$  is a function of  $\kappa a$ . It follows from equation (3) that when the value of  $\kappa a$  exceeds 100, the variation of mobility with particle-size is, for the present purposes, negligible, and in this case the mobilities of different particles are proportional to their surface-charge densities.

Thus equation (2) becomes

$$(u - u_R) = (u_p - u_R) f_p + (u_F - u_R) f_F \quad . \quad . \quad (4)$$

where  $u$ ,  $u_p$ ,  $u_F$ ,  $u_R$  are the cataphoretic mobilities of particles of latex-rubber, of protein, of "resin" and of rubber hydrocarbon respectively.

The values of these different mobilities will depend upon the ionic environment of the particles. Thus, in one particular environment we have

$$(u' - u_R') = (u_p' - u_R') f_p + (u_F' - u_R') f_F \quad . \quad . \quad (5)$$

and in a second environment, providing  $f_p$ ,  $f_F$  remain unchanged,

$$(u'' - u_R'') = (u_p'' - u_R'') f_p + (u_F'' - u_R'') f_F \quad . \quad . \quad (6)$$

Since the values of the mobilities in the two cases are readily determined by experiment, the value of  $f_p$  and  $f_F$  can be calculated.

In practice, the method was applied by determining the mobility- $\rho_H$  relations in buffer solutions of ionic strength 0.01 for particles of pure rubber hydrocarbon, of protein, of "resin" and of latex-rubber. The value of  $\kappa a$  was in no case less than 150, so that the effect of small variations in the particle size could be neglected.

<sup>11</sup> Henry, *Proc. Roy. Soc.*, 1931, **A**, **133**, 106.

### Experimental.

The measurements of electrophoretic mobility were made with a micro-cataphoresis apparatus of the capillary-tube type, in conjunction with a slit-ultramicroscope. Determinations of  $p_H$  were made by means of an antimony electrode.

### The Rubber Hydrocarbon.

Crepe-rubber was extracted with acetone for 96 hours to eliminate the "resin." The rubber was then dissolved in chloroform and emulsified with alcohol and water containing caustic soda, the final concentration of alkali being approximately normal. The emulsion was repeatedly shaken with fresh quantities of caustic soda solution in order to free the rubber from proteins. The emulsion was finally washed until the  $p_H$  of the washings was less than 8. The emulsion was then stabilised with a little

FIG. 1.—Constituent colloids of latex in solutions of ionic strength 0.01.

ammonia, the  $p_H$  being 9, and shaken vigorously with water. The aqueous dispersion of the purified rubber was then boiled under reduced pressure to remove the volatile solvents. The properties of the rubber dispersion were not affected by this boiling, since similar mobility values were obtained with dispersions from which the solvents had been removed by aeration.

The results for the dispersion of the rubber hydrocarbon are shown in Fig. 1, as curve 3. It will be seen that as the  $p_H$  is decreased, the negative charge on the rubber globules falls owing to the adsorption of hydrogen ions, and finally the charge becomes zero at  $p_H\ 2.4 \pm 0.1$ .

### The Protein of Latex.

Ammonia-preserved plantation latex of 35 per cent. concentration was coagulated by dilute acetic acid, and the clear filtered "serum" was saturated with ammonium sulphate to precipitate the protein. The precipitate was filtered off, redissolved in acid of  $p_H\ 2.0$ , and reprecipitated with ammonium sulphate. The precipitate was collected, dissolved in water, and the excess electrolyte was removed by electrodialysis.

In order to determine the cataphoretic mobility of the protein, it was

necessary to make measurements with protein-covered silica particles, since the protein does not give sols containing visible particles. The results are given in Fig. 1 (curve 1). The isoelectric point of the protein or mixture of proteins in the solutions employed is  $p_H 4.40 \pm 0.07$ .

### The "Rubber-Resin."

The acetone solution of "resin" obtained in the preparation of the rubber hydrocarbon was mixed with distilled water to give a dispersion of the "rubber-resin," excess acetone being removed by aeration. The mobility- $p_H$  relation for "resin" particles is expressed as curve 2 of Fig. 1. The negative charge on the particles is due in part to the ionisation of the acids in the "resin," and partly to ionic adsorption. Thus, as the  $p_H$  is decreased, the ionisation of the acids is repressed, and in sufficiently acid solutions the adsorption of hydrogen ions is sufficient to reverse the charge, the isoelectric reaction being  $p_H 2.1 \pm 0.1$ .

### The Latex.

Measurements were made with ammonia-preserved Hevea latex, of total solid content 39.1 grams/100 c.c., about five months after tapping.

FIG. 2.—Diluted plantation latex in solutions of ionic strength 0.01.

× Acetate buffers; O Phosphate buffers.

Curve	1	2	3	4	5	6	7	8
Conc. of Latex per cent.	0.0016	0.008	0.39	1.18	3.91	6.76	8.98	19.5

Latices of various concentrations were prepared by diluting this plantation latex, and, in the case of the higher concentrations of latex, ionic impurities were removed by electrodialysis with a collodion membrane. The results are given in Fig. 2. From the graphs it will be seen that the cataphoretic behaviour of latex depends upon the degree of dilution.

Both the slope of the mobility- $p_H$  curve and the isoelectric point of the latex dispersion are dependent upon the latex concentration. For low concentrations of latex, it was possible to make measurements over a large  $p_H$  range, but for higher concentrations, the measurement of mobility became difficult in solutions of  $p_H > 7$ , since usually in such solutions no aggregation of the latex globules took place, and owing to the large number of globules present, the intensity of reflected and diffracted light was too great for convenient observation.

### Discussion.

The slopes of the mobility— $p_H$  curves for latex of low concentrations are appreciably greater than those for the rubber hydrocarbon, the protein, and the "resin," indicating that the amounts of protein and of "resin" on the rubber surface may change continuously with  $p_H$ . Thus the solubilities of these two substances increase with  $p_H$ , and consequently in highly diluted latex, the rubber particles may be quite uncovered in alkaline solutions (Fig. 2, Curve 1).

In acid solutions ( $p_H$  about 4) the curves 3, 4, 5 of Fig. 2 indicate mobilities which are somewhat greater than those given by the protein curve (Fig. 1, curve 1). There is thus a slight discrepancy from the theory, since it would be expected that the slopes of the curves for latex would begin to fall on the acid side of the isoelectric points.

As the latex concentration is increased, the mobility— $p_H$  curve approaches more nearly that of the protein, showing that the fraction of the globule surface covered with protein increases as the concentration of protein is increased. The curves for the highly diluted latex do not, therefore, obey the equation for the mobility— $p_H$  slopes

$$\left(\frac{du}{dp_H} - \frac{du_R}{dp_H}\right) = \left(\frac{du_P}{dp_H} - \frac{du_R}{dp_H}\right)f_P + \left(\frac{du_F}{dp_H} - \frac{du_R}{dp_H}\right)f_F \quad (7)$$

hence the values of  $f_P$  and  $f_F$  cannot be derived from substitution in equations (5) and (6).

However, by a method of successive approximations, the values of  $f_P$  and  $f_F$  for the "average" latex globule at a given  $p_H$  can be calculated. At a particular  $p_H$ , the values of  $u$ ,  $u_P$ ,  $u_F$ ,  $u_R$  can be measured, and, in addition, the approximate values of  $f_P$  and  $f_F$  can be obtained from the measured values of the mobilities, since near the isoelectric point, when the latex curve approaches the protein curve, we assume

$$f_P \doteq \frac{u - u_R}{u_P - u_R} \quad \text{and} \quad f_F = 1 \doteq f_P,$$

and by substituting these values in the equation (7), it is possible to obtain the theoretical value of  $du/dp_H$  at the  $p_H$  of measurement, since the slopes of the other curves are known at this  $p_H$ . From the approximate equation (7) and the more exact equation (4), the values of  $f_P$  and  $f_F$  can be obtained. The mobilities in equation (4) are correct to  $\pm 5 - 7$  per cent., the slopes substituted in equation (7) are measurable to  $\pm 10 - 15$  per cent., and the approximate values of  $f_P$  and  $f_F$  can be calculated to  $\pm 10$  per cent. near the isoelectric point. The errors in the final values of  $f_P$  and  $f_F$  vary with the  $p_H$  for the lower concentrations of latex, but do not exceed  $\pm 10$  per cent. at  $p_H 7$ . The errors are greater in the case of curves 1 and 2 of Fig. 2, where the protein covering appears to be incomplete at the isoelectric point.

By this method the change in the surface composition of the "average" rubber globule in latex with varying  $p_H$  could be obtained. The results are shown in Figs. 3 and 4.

In Fig. 5 is shown the variation in the surface composition of the "average" rubber-globule at  $p_H 8.0$  as a function of the concentration of latex. It will be noted that the extreme surface of the "average" rubber globule is entirely composed of protein at this  $p_H$  when the concentration has risen to about 12 per cent. total-solids content.

Hence, the outer surface of the rubber globules in ordinary undiluted Hevea latex at  $p_H$  8.0 is entirely of protein character, and the slope of the  $f_p - p_H$  curve indicates that they are still completely covered at the

$p_H$  of the preserved latex, *i.e.*,  $p_H$  10. Similarly, it is evident that the rubber globules in ammonia-preserved 60 per cent. latex (obtained by centrifugal creaming of ordinary plantation latex) are also completely covered with protein.

It should be noted that these results are not necessarily at variance with the possible presence of the protein as a lipoid-protein complex although they agree more naturally with the simpler view as to the independence of the protein and the "rubber-resin."

FIG. 5.—Variation in surface composition of rubber globule at  $p_H$  8.0 with dilution of the latex. 1. Protein. 2. "Resin."

### Summary.

1. A method for the surface analysis of colloidal particles is outlined.
2. The electrophoretic behaviour of the protein, "resin," and rubber hydrocarbon of the latex of *Hevea brasiliensis* is described.
3. The electrophoretic behaviour of the diluted ammonia-preserved plantation latex has been investigated, and it is shown that the amounts of protein and "rubber resin" adsorbed at the surface of the rubber globule are dependent upon the degree of dilution of the latex and upon the  $p_H$  of the serum.
4. The fractions of the rubber-globule surface covered with protein and with "rubber resin" are calculated, and their variation with latex-dilution and the  $p_H$  of the serum is plotted.
5. The rubber globules at  $p_H$  8.0 are completely covered with a protein layer, provided the latex is not diluted below 12 per cent. total solids content.

# THE TITRATION CURVE OF FEATHER KERATIN.

BY J. B. SPEAKMAN AND F. TOWNEND.

*Received 23rd March, 1936.*

Recent years have seen great advances in knowledge of the fine structure of animal fibres, but an exact knowledge of the composition of keratin, in terms of its constituent amino acids, seems to be needed if further progress is to be made. Although wool is the most important keratin from an industrial point of view, it would be difficult to accept it as the most suitable keratin for amino-acid analysis in view of its variable composition.<sup>1</sup> In addition, wool gives a very ill-defined X-ray fibre diagram and is not, therefore, a suitable subject for an attempt to obtain a complete interpretation of the structure of the keratin molecule from the combined results of X-ray and amino-acid analysis. On the other hand, feather keratin, particularly the quill of seagull feather, is remarkable for the perfection of its X-ray photograph, which is regarded as "the richest fibre photograph so far observed."<sup>2</sup> At the time seagull quill was selected for amino-acid analysis, however, its cell structure was believed to be homogeneous, but a recent examination of the cross-section of trypsin-retted quill has shown it to consist of at least two types of cell.

Although no work has been carried out on the composition of seagull quill, goose feather has been the subject of many investigations. Using the Fischer ester method, Abderhalden and Le Count<sup>3</sup> obtained the data summarised in Table I, which also includes Block and Vickery's more recent determinations<sup>4</sup> of the basic amino-acids in goose feather. Assuming that every amino-acid is incorporated in peptide chains through  $\alpha$ -amino- and associated carboxyl-groups, the two sets of data account for only 35.4 per cent. of the feather. To this value must be added that for cystine, which according to Wilson and Lewis' results<sup>5</sup> for different types of feather seems to be of the order of 9 per cent., as shown in Table II. In the case of goose feather, therefore, no more than 44 per cent. of the

keratin has been identified, but the preceding data, even though incomplete, have a definite value in connection with later argument concerning the composition of feather keratin.

As a preliminary to analytical work on seagull quill, it was decided to determine its titration curve, because corresponding work on wool keratin <sup>6</sup> together with related studies of its elastic properties in media <sup>7</sup> of varying  $p_H$ , have proved useful in giving a general indication of the constitution of the molecule. For example, if seagull quill is similar to wool, its maximum acid-combining capacity should establish the content of basic amino-acids and show whether Block and Vickery's determinations of the basic amino-acids in goose feather are valid for seagull quill. Alternatively, if there is any foundation for Astbury's enquiry as to whether it may not be that "the growth of feathers finds its origin in the

development of further keratin chains by the formation of *lateral* peptide linkages? " <sup>8</sup> the maximum acid-combining capacity of feather should be less than would be expected from the content of basic amino-acids. Finally, the titration curve of wool keratin shows an isoelectric range from  $p_H$  5 to 7, which implies equivalence between the dicarboxylic acids and the amide nitrogen and basic amino-acids. Should the titration curve of feather keratin show a similar isoelectric range, the same equivalence rule would hold, and the total content of dicarboxylic acids in seagull quill would then be capable of deduction.

### Experimental.

**Purification of Feather.**—Because there is little difference between the X-ray photographs of feather from various types of gull, and because of the difficulty of collecting large quantities of material for analysis, the tail and wing feathers of mature herring gull, black-backed gull and gannet were purified and mixed as follows. After rejecting those quills which showed an opaque white spotting, the remainder were cut just below the first barbs, at the junction of the translucent quill and the pith-containing portion of the rachis. The inferior umbilicus of each quill was then cut away, the feather sheath removed from the outside, and the quill bisected longitudinally. After cleaning each half by scraping both sides with a knife, the quill was cut into pieces from  $\frac{1}{4}$  to  $\frac{1}{2}$  inch long. When a sufficient quantity of quill had been prepared in this way, it was freed from wax by extraction in an all-glass soxhlet apparatus for two days with alcohol, two

days with ether, and two days again with alcohol. Finally, the alcohol retained by the feather was removed by washing in several changes of distilled water over a period of 3 or 4 days.

#### Determination of the

**Titration Curve.**—Since the isoelectric point or region of feather keratin was unknown, the purified feather was merely allowed to attain equilibrium with distilled water at 22.2° C., the final  $p_H$  being 4.6, before being used for determinations of acid- and alkali-combining capacity. Approximately 1-gram samples of the air-dry keratin were dried over phosphorus pentoxide *in vacuo* until constant weight was attained, a period of two months or more being necessary. Except at low  $p_H$ , where 2 g. of feather were used to increase the precision of the results, each 1-gram sample was transferred to 100 cc of HCl or NaOH solution of known  $p_H$  at 22.2° C., precautions being taken

to exclude carbon dioxide from the alkaline solutions during equilibration and  $p_H$  measurement. Preliminary experiments showed that equilibrium was attained between feather and acid and alkaline solutions in 5 and 10 days respectively, such long times being necessary because the feather was used in fairly large pieces. The amounts of acid and alkali combined with the feather were calculated from the measurements of initial and final  $p_H$ , except at extremes of  $p_H$ , where aliquots of the original and equilibrium solutions were titrated with alkali or acid. From the results, which are collected in Table III, the titration curve shown in Fig. 1 was constructed.

FIG. 1.

### Discussion of Results.

If the basic amino-acids of feather are incorporated in long peptide chains through  $\alpha$ -amino and associated carboxyl groups, as in the case of wool, acid must combine with feather through the terminal amino-, guanido- and iminazole-groups of lysine, arginine and histidine, respectively. Taking Block and Vickery's data for the amounts of these amino-acids in goose feather, its maximum acid-combining capacity should be 38.1 c.c. of  $N/1$  hydrochloric acid per 100 g. dry feather, a value in good agreement with that found experimentally for seagull quill, *viz.*, 41 c.c. That the theoretical result should be low is understandable in view of the great difficulty of isolating basic amino-acids quantitatively, and it seems reasonable to assume that Block and Vickery's determinations of the basic amino-acids in goose feather are equally valid for seagull quill. Support for this view is to be found in the following approximate determination of the arginine content of seagull quill by the van Slyke procedure.

49.49 g. dry seagull quill were hydrolysed by boiling for 30 hours with 400 c.c. of 20 per cent. hydrochloric acid under a reflux condenser. After concentration to a syrup, the solution was made alkaline with lime, diluted to 2 litres, and distilled under reduced pressure. From the amount of ammonia evolved, the amide nitrogen content of the feather was found to be 15.12 mgm./g., but the best value, as deduced from 10 determinations on three hydrolysates, is 14.90 mgm./g. Following the determination of amide nitrogen, the lime was filtered off and washed well with hot water. The filtrate was then made up to two litres after neutralisation with hydrochloric acid, and 350 c.c. of concentrated hydrochloric acid were added. After heating the solution to 90° C. on the water bath, the bases were precipitated by adding 250 g. phosphotungstic acid dissolved in 1 litre of water. The phosphotungstates were allowed to separate for three days in the ice chest, before being filtered off and washed in four litres of an ice-cold solution of 2.5 per cent. phosphotungstic acid in  $N/1$  hydrochloric acid. Amyl alcohol-ether mixture, previously extracted with hydrochloric acid, was used to redissolve the base-phosphotungstates in the manner recommended by van Slyke, and the solution was made up to 500 c.c. The total nitrogen content of the phosphotungstates was found to be 1654.0 mgm., or 33.41 mgm./g. dry seagull quill. This value is far in excess of what would be expected from Block and Vickery's determinations of the basic amino acids in goose feather, but it is well known that the precipitate of phosphotungstates is liable to contain amino-acids other than the hexone bases.\* When the phosphotungstates were allowed to separate at room temperature instead of at 0° C., the nitrogen content of the precipitate was equivalent to 24.82 mgm./g. From this value must be subtracted 5.00 mgm./g. for the cystine content of the precipitate, as shown below, so that the nitrogen content of the basic amino-acids in seagull quill is 19.82 mgm./g. While this result accords well with the theoretical value of 19.1 mgm./g. deduced from Block and Vickery's determinations of the basic amino-acids in goose feather, too much stress cannot be placed on the agreement because the quantity of amino-acids precipitated by phosphotungstic acid varies with temperature.

As regards the main solution of the phosphotungstates precipitated at 0° C., aliquots were boiled with 50 per cent. caustic potash solution for six hours, and six determinations of the amount of ammonia evolved gave an average value of 10.83 mgm. nitrogen per 10 c.c. of solution. The latter contained cystine, which, according to van Slyke, liberates 18 per cent. of its nitrogen as ammonia under the above conditions. Two determinations by the Benedict-Denis method of the amount of sulphur in the solution of phosphotungstates showed that the cystine nitrogen was 4.99 mgm./10 c.c., so

\*Kernot and Knaggs, *Biochem. J.*, 1928, **22**, 528; Kernot, Knaggs and Speer, *ibid.*, 1930, **24**, 379.

that the correction to be applied to the above value for the nitrogen liberated on boiling the phosphotungstates with caustic potash is 0.90 mgm. Since arginine liberates half its nitrogen as ammonia under the above conditions, the total arginine nitrogen is  $2 + 9.93$  mgm. per 10 c.c. of the solution of phosphotungstates, or 20.07 mgm./g. of feather, and the arginine content of the feather is 6.23 per cent. That this value should exceed that obtained by Block and Vickery is not surprising in view of the fact that the isolation method yields low results, and the van Slyke method high results. Actually, some increase in the arginine content of feather above Block and Vickery's value is needed to account completely for its acid-combining capacity, so that the above determination of the arginine content of seagull quill serves to confirm the view that Block and Vickery's data for goose feather are equally applicable to seagull quill. It must therefore be concluded that the maximum acid-combining capacity of feather keratin is accounted for by the basic side chains of arginine, lysine and histidine, and the balance of evidence is opposed to the possibility\* that the terminal amino- and guanido-groups of lysine and arginine may take part in the formation of lateral peptide linkages.

The second point of interest in the titration curve of seagull quill is the fact that it shows an isoelectric range from about  $p_H$  4.3 to 6.3. By analogy with wool, which shows a similar range from  $p_H$  5 to 7, the isoelectric range of feather may be taken to imply equivalence between its dicarboxylic acids and the basic amino-acids and amide nitrogen. According to this view, the dicarboxylic acid nitrogen of feather should be 14.90 (amide nitrogen)  $+ 5.34$  (basic amino-acids) = 20.24 mgm./g. As shown in Table I., however, the amounts of dicarboxylic acid isolated from goose feather fall far short of this requirement, and correspond with only 3.38 mgm. nitrogen per gram of feather. The discrepancy is so great that the total quantity of dicarboxylic acids in seagull quill was estimated in the following manner. In the preceding determination of arginine, the solution remaining from the precipitation of phosphotungstates contained the dicarboxylic acids of 49.49 g. of feather keratin. It was freed from phosphotungstic acid by extraction with amyl alcohol-ether mixture and then concentrated under reduced pressure to remove excess hydrochloric acid. After making the syrup strongly alkaline with lime, it was diluted to a volume of 1 litre, and the calcium salts of the dicarboxylic acids in 600 c.c. of the solution were precipitated with eight volumes of alcohol. When the mixture had stood overnight, the precipitate was filtered off and washed well with alcohol. Damodaran's procedure<sup>10</sup> for estimating dicarboxylic acids was not followed, because it was found that the presence of calcium chloride in the solution of the calcium salts of dicarboxylic acids interfered greatly with their precipitation by alcohol, the precipitate being far too impure to afford a reliable estimate of the dicarboxylic acid content of seagull quill. The impure calcium salt precipitate was therefore redissolved in warm water, filtered to remove a slight turbidity, and then made up to a volume of 2 litres. Aliquots of the solution were withdrawn and precipitated with various volumes of alcohol, the nitrogen content of the precipitates being determined by Kjeldahl's method. The results are summarised in Table IV., illustrated by Fig. 2.

The curve shows an abrupt break when the nitrogen content of the precipitate is 20 mgm./g. feather, a value in remarkably close agreement with the theoretical requirement of 20.24 mgm./g. for the nitrogen content of the dicarboxylic acids in seagull quill. It is therefore evident that the dicarboxylic and basic amino-acids are incorporated in peptide chains through  $\alpha$ -amino- and associated carboxyl-groups. A large part of the acid side chains are combined with ammonia to form acid amides, the remainder being combined with the basic side chains to form salt linkages of the type previously shown to exist in wool keratin.<sup>7</sup> Just as in the latter case, there

<sup>10</sup> Damodaran, *Biochem. J.*, 1931, **25**, 2123.

is exact equivalence between the basic side chains and those acid side chains not present as acid amides. With both wool and feather keratin, the presence of the necessary amount of dicarboxylic acids to account for amide nitrogen and basic amino-acids according to the salt linkage hypothesis, has also been demonstrated in large-scale attempts to isolate the acids. As regards feather keratin, separation of the acids from the mixture is not yet complete,

FIG. 2.

but 9.1 per cent. of glutamic acid and 2.4 per cent. of *i*-aspartic acid have so far been isolated, corresponding with a dicarboxylic acid nitrogen content of 11.3 mgm./g. of feather.

In conclusion, it will be observed that the titration curve of feather keratin, unlike that of wool, does not show the step due to lysine salt linkages at  $p_H$  10 to 11. No significance need be attached to its absence because the quill undergoes destructive attack in the more strongly alkaline solutions during the 10 days needed to attain equilibrium.

### Summary.

The titration curve of seagull quill shows an isoelectric range from  $p_H$  4.3 to 6.3, suggesting that the dicarboxylic acids are exactly equivalent to the basic amino-acids and amide nitrogen. Support for this, the salt-linkage hypothesis, has been derived from determinations of the amide nitrogen and dicarboxylic acid contents of the keratin. The dicarboxylic acids were found to be equivalent to the amide nitrogen and the basic amino-acids, the latter being estimated from the maximum acid-combining capacity, which accords well with Block and Vickery's determinations of the basic amino-acids in goose feather.

# THE DECOMPOSITION OF HYDROGEN SULPHIDE AND WATER ON MOLYBDENUM FILAMENTS.

By F. E. T. KINGMAN.

*Received 24th March, 1936.*

In the course of an investigation of molybdenum catalysts some preliminary studies have been made of the decomposition of hydrogen sulphide and water on molybdenum filaments.

## Apparatus.

The molybdenum filament, 20 cm. long and 0.006 cm. diameter was spotwelded at each end to stout tungsten leads fused through the ends of the pyrex reaction vessel, which was cylindrical in form, 25 cm. long, and 2.5 cm. diameter. The reaction vessel was connected to a Pirani gauge and gas pipette, and the whole apparatus could be evacuated to  $10^{-5}$  mm. by a mercury pump backed by a Cenco "Hyvac" oil pump.

The Pirani gauge consisted of a platinum filament maintained at 100° C. Blank experiments showed that no decomposition of either hydrogen sulphide or water took place on this filament. The gauge was calibrated for hydrogen against a McLeod gauge, which was cut off from the reaction system during experiments.

The temperature of the molybdenum filament was determined by measuring its resistance and calculating from the resistance-temperature curve for molybdenum; no corrections were made for variation in temperature along the filament.

## 1. Experiments with Hydrogen Sulphide.

Hydrogen sulphide prepared from hydrochloric acid and antimony sulphide, was washed with water, dried over phosphorus pentoxide, and distilled. Hydrogen was purified by passage through a heated palladium tube.

Experiments were carried out by admitting 0.03 c.c. of hydrogen sulphide, giving an initial pressure of 0.088 mm., and following the course of the reaction by freezing out the residual hydrogen sulphide with liquid air and measuring the pressure of hydrogen on the Pirani gauge.

**Results.**—The results obtained from experiments at temperatures of 400°–685° C. are shown in Fig. 1, the logarithm of the residual pressure of hydrogen sulphide being plotted against the time. Analysis of the results showed that the reaction could be accurately represented by a mono-molecular equation, *i.e.*,

$$-\frac{dp}{dt} = kp \quad . \quad . \quad . \quad . \quad . \quad (1)$$

$$\text{whence} \quad k = \frac{1}{t} \log_e \frac{p_0}{p} \quad . \quad . \quad . \quad . \quad . \quad (2)$$

where  $p$  = pressure of hydrogen sulphide at time  $t$ .  
 $p_0$  = initial pressure of hydrogen sulphide,

so that, since the decomposition of hydrogen sulphide results in the liberation of an equal volume of hydrogen,

$$p_0 - p = \text{pressure of hydrogen at time } t.$$

For a constant value of  $p_0$ ,

$$kt = A - \log_e p \quad (A = \log p_0)$$

or

$$k_1 t = B - \log_{10} p.$$

Thus by plotting the values of  $\log_{10} p$  against  $t$  for various temperatures, a series of straight lines are obtained (Fig. 1) from the slopes of which the relative value of  $k$  can be determined for each temperature. From the values thus obtained, the energy of activation can be calculated using the usual Arrhenius equation. The heat of activation for this reaction was thus found to be 25,000 Cals.

FIG. 1.

The decomposition of hydrogen sulphide must result in the liberation of an equimolecular amount of hydrogen, and, in addition, the production of free sulphur or of molybdenum sulphide. In these experiments it was observed that after 0.9 c.c. of hydrogen sulphide had been decomposed, the solid product of the reaction became visible as a dark continuous film on the walls of the reaction vessel. This product was distilled into a small liquid-air trap, the latter cut off, and the product examined. Owing to the small amount available, it was not possible to analyse the product completely, but it was shown that no molybdenum was present. This result was checked by comparing the weight of the filament with that of an equal length of the original molybdenum wire; there was no change in weight.

Thus, the decomposition of hydrogen sulphide on a molybdenum filament under the conditions of these experiments results in the formation of hydrogen and free sulphur. No production of molybdenum sulphide takes place, the sulphur formed being continuously removed by evaporation from the filament and condensation on the cold walls of the reaction vessel. This is also in agreement with the experimental fact that no inhibition of the reaction by the products can be observed.

## 2. Decomposition of Water Vapour.

The apparatus used was similar to that described above. A tube containing water (freed from dissolved gases) was kept in melting ice, thus maintaining a constant vapour pressure, and a known volume of water vapour at this pressure was admitted to the reaction system so as to give an initial pressure of water vapour of 0.1 mm. The course of the reaction was followed by a similar method to that employed in the hydrogen sulphide experiments, the water vapour being frozen out at intervals by liquid air, and the residual pressure of hydrogen measured on the Pirani gauge.

It was found that no appreciable reaction could be observed at temperatures below 800° C., the experiments described were therefore carried out at 800°–1200° C., and some typical results are shown in Fig. 2.

The reaction which occurred resulted in the formation of a film of molybdenum oxide on the surface of the filament. At temperatures below 1000° C. this film was not volatilised and retarded the reaction. Thus, when a second admission of water vapour was made at 800° C., the rate

FIG. 2.

of reaction fell to a negligible value. The oxide film could easily be removed by flashing for a short time at 1500° C.

At temperatures above 1000° C. it was found that the oxide film volatilised as quickly as it was formed, so that when a second admission of water vapour was made without flashing the wire, the rate of reaction was the same as with a flashed filament.

In these experiments carried out at temperatures above 1000° C., it was also observed that the pressure of hydrogen, after increasing steadily to 0.07–0.08 mm. became constant and then slowly decreased. This phenomenon was not quantitatively reproducible, the magnitude of the decrease in pressure being dependent on factors apparently outside the degree of experimental control. This decrease in pressure can be accounted for by assuming that some of the hydrogen molecules are dissociated at the heated filament and the atoms are then taken up by the molybdenum oxide film on the walls of the reaction vessel, the capricious nature of the effect being due to variations in the surface of this film.

The pressure-time curves for the decomposition of water vapour are thus more complex than those obtained in the hydrogen sulphide experiments, and it has not been possible to analyse the results even for the early stages of the reaction, where the secondary reaction involving the disappearance of hydrogen might be expected to have less effect. The heat of activation of the primary process of the decomposition of water to give hydrogen and molybdenum oxide has been obtained by determining the

time ( $t$ ) taken to produce a definite pressure of hydrogen. The heat of activation is then calculated from the formula :

$$2.303 \log_{10} \frac{t_1}{t_2} = \frac{Q}{R} \left( \frac{1}{T_1} - \frac{1}{T_2} \right)$$

where  $t_1$  and  $t_2$  are the times taken to reach a given pressure at temperatures  $T_1$  and  $T_2$  respectively.

Plotting  $\log t$  for the times taken to give pressures of 0.01, 0.02 and 0.03 mm. against  $1/T$  for temperatures of 800°-1200° C., a series of three straight parallel lines are obtained (Fig. 3) from which the value of the energy of activation is 43,000 Cals. It will be noted that at low concentrations of the oxide film there is no change in the activation energy of the reaction as the temperature is increased beyond that necessary to volatilise the oxide film.

FIG. 3.

### Summary.

1. The decomposition of hydrogen sulphide at a pressure of 0.1 mm. on a molybdenum filament has been studied over a temperature range of 400°-685° C. The reaction results in the formation of hydrogen and free sulphur, the rate of reaction being proportional to the pressure of hydrogen sulphide. The energy of activation of the reaction is 25,000 Cals.

2. The decomposition of water vapour on a similar molybdenum filament at temperatures of 800°-1200° C. results in the formation of molybdenum oxide and hydrogen, followed, at temperatures above 1000° C. by the formation of hydrogen atoms, which are absorbed by the molybdenum oxide film on the walls of the reaction vessel. The heat of activation of the decomposition reaction is 43,000 Cals.

## KINETICS OF RECOMBINATION OF BROMINE-ATOMS II.

BY E. RABINOWITCH AND W. C. WOOD.

*Received 26th March, 1936.*

### I. Introduction.

In a previous paper<sup>1</sup> we described an optical method for the determination of the stationary dissociation of  $\text{Br}_2$  molecules in an illuminated vapour. Because of thermal effects we were unable to calculate the exact degree of dissociation except when the dissociation takes place in a helium atmosphere. Later<sup>2</sup> we found that thermal effects can be reduced by using smaller halogen-concentrations. This is shown by comparing the formulæ (1) and (2), derived<sup>1</sup> for the two effects in question :

$$\Delta_{\text{therm.}} = \frac{3}{32} \frac{Q}{\kappa T_0} (\simeq \text{const.} \times [\text{Br}_2]) \quad (1)$$

$$\Delta_{\text{homo. diss.}} = \frac{1}{[\text{Br}_2]} \sqrt{\frac{2N_{\text{hv}}}{C_1[X]}} \left( \simeq \text{const.} \times \frac{1}{\sqrt{[\text{Br}_2]}} \text{ if } [X] = \text{const.} \right) \quad (2)$$

$$\frac{\Delta_{\text{therm.}}}{\Delta_{\text{homo. diss.}}} = \text{const.} \times [\text{Br}_2]^{\frac{3}{2}} \quad (3)$$

$\Delta \left( = \frac{\Delta[\text{Br}_2]}{[\text{Br}_2]} \right)$  is the relative change of concentration of bromine-molecules caused by illumination,  $Q$  the energy (in Cals.) and  $N_{\text{hv}}$  the number of quanta absorbed per sec. per c.c. of the gas,  $[X]$  the concentration of molecules acting as third bodies in the recombination of the atoms,  $\kappa$  the thermal conductivity, and  $C_1$  the velocity constant of the recombination. At low concentrations of bromine,  $Q$  and  $N_{\text{hv}}$  are proportional to  $[\text{Br}_2]$ .

The darkened areas in Figs. 3a and 3b show the parts played by the thermal effects : (A) in the old experiments with 4.5 mm. of  $\text{Br}_2$ , and (B) in the new experiments with a  $\text{Br}_2$  pressure about 0.3 mm.

### II. Experimental.

The scheme of the apparatus was shown in Fig. 1 in the previous papers.<sup>1, 2</sup> The second paper<sup>2</sup> contains also the description of the exact computation of  $N_{\text{hv}}$ . Fig. 1 shows the spectral energy-distribution of the

<sup>1</sup> E. Rabinowitch, H. L. Lehmann, *Trans. Faraday Soc.*, 1935, **31**, 689.

light  $L$  from the 1500 watt carbon arc used for dissociation, filtered through 1 cm. of saturated  $\text{CuSO}_4$ -solution. The lower curve shows the intensity

FIG. 1.—Energy-distribution of the illuminating light  $L$ , and its absorption by bromine.

distribution of the light absorbed by bromine.<sup>3</sup> By graphical integration, the mean extinction coefficient of bromine for the light  $L$ , and the mean wave-length of the light absorbed were found to be,

$$\bar{\alpha}_L = 3.75 \\ \lambda_L = 4330 \text{ \AA.}$$

The first value was confirmed by direct measurement of the absorption of  $L$ -light by bromine at higher pressures and extrapolation to  $p(\text{Br}_2) = 0$  (Fig. 1 A inset). The mean absorption of  $L$ -light in the cell was less than 2 per cent. With the above-calculated values of  $\bar{\alpha}_L$  and  $\lambda_L$ , and the calibration-factor of the thermopile-galvanometer combination deter-

mined previously, the following formulæ were derived for the calculation of  $N_{hv}$  and  $Q$ :

$$N_{hv} = 1.99 \times 10^{13} \times p_{\text{mm.}}(\text{Br}_2) \times L_{\text{cm.}} \frac{\text{quanta}}{\text{sec.} \times \text{c.c.}} \quad (4)$$

$$Q = 2.21 \times 10^{-6} \times p_{\text{mm.}}(\text{Br}_2) \times L_{\text{cm.}} \frac{\text{g cals.}}{\text{sec.} \times \text{c.c.}} \quad (5)$$

$L$  being the deflection of the galvanometer in cm.

The light beam  $J$  from a 6v. filament lamp, used for the measurement of  $[\text{Br}_2]$  and  $\Delta[\text{Br}_2]$ , was filtered through infra-red-absorbing glass (Jena BG17) and blue glass (Jena BG12). It contained wave-lengths 4000-4800 Å. and the mean extinction-coefficient of bromine for it was found to be (at low pressures)  $\bar{\alpha}_J = 6.0$ . The absorption of  $J$  along the cell ( $d = 12$  cm.) is 7-10 per cent. only, and the use of a mean  $\bar{\alpha}$ -value is therefore justified.

<sup>3</sup> Cyanogen-bands are prominent in the part of the spectrum strongly absorbed by bromine; this affects somewhat the exactness of the determination of  $N_{hv}$ , because the intensity of these bands is variable even when the arc burns very steadily. The extinction coefficients used for calculation were those given by Ribaud; we tested several points of his curve and found them to be correct.

The relative change of concentration  $\Delta \equiv \frac{\Delta[\text{Br}_2]}{[\text{Br}_2]}$  was calculated from the relative change of transmission  $\Delta J/J$  by means of the equation<sup>4</sup>

$$\Delta J/J = \Delta \times \bar{\alpha}_J p_{\text{atm.}}(\text{Br}_2) \left. \frac{d \log_e 10}{p_{\text{mm.}}(\text{Br}_2)} \right\} \times \Delta \quad (6)$$

By using (4) and (6) for the determination of  $N_{\text{av}}$  and  $\Delta$  respectively, the velocity-constant  $C_1$  in (2) was calculated from measurements of  $\Delta J$ ,  $J$  and  $L$ .

The bromine-pressure was measured by means of a manometer filled with sulphuric acid. Another method—which gives more exact values at low pressures—is to calculate  $p(\text{Br}_2)$  from the absorption of the light  $J$ , using the above-determined extinction-coefficient  $\bar{\alpha}_J = 6.0$ .

### III. General Results.

We determined the stationary dissociation of illuminated  $\text{Br}_2$  in mixtures with  $\text{He}$ ,  $\text{H}_2$ ,  $\text{N}_2$ ,  $\text{O}_2$ ,  $\text{CH}_4$  and  $\text{CO}_2$ . Figs. 2 and 3 show, as examples, the results obtained with  $\text{H}_2$  and  $\text{N}_2$ .

The abscissæ are the pressures of the gases in mm., the ordinates the observed changes in transmission  $\Delta J$ . The thermal effect (shown by the darkened area) forms the whole of the effect observed in pure bromine, but only a small part of it in presence of foreign gases. The unbroken lines in Figs. 2 and 3 are the "theoretical" curves: straight lines in the region of heterogeneous recombination, (where the molecules recombine on the walls) and inverse-square-root curves in the region of homogeneous recombination (according to equation (2)). The agreement between experiment and theory is remarkable.<sup>5</sup>

FIG. 2.—Effects observed in hydrogen.

The dependence of the effect on light intensity  $L$  is shown by Fig. 4. The abscissæ are the pressures  $p_{\text{mm.}}(\text{X})$  ( $\text{X} = \text{argon}$  in this particular case) and the ordinates the exponents  $\alpha$  of the equation

$$\Delta J = \text{const.} \times L^\alpha \quad (7)$$

<sup>4</sup> The method, by which  $\Delta$  can be calculated at higher  $p(\text{Br}_2)$  values is described in the last part of this paper.

<sup>5</sup> We discussed elsewhere—see *Z. physik. Chemie (B)*, 1936, why the influence of the homogeneous recombination is relatively strong at low pressures, whereas that of the wall recombination disappears as soon as the maximum of  $\Delta J$  is passed.

FIG. 3a.—Effects observed in nitrogen;  
 $p_{(\text{Br}_2)} = 0.28 \text{ mm.}$

The value of  $x$  drops from  $x = 1$  (which is the theoretical value for both the thermal effect and the *heterogeneous* dissociation equilibrium) to  $x = \frac{1}{2}$ , which is the value required by (2) for the homogeneous dissociation-effect.

In the case of bromine a large range of halogen pressures can be used. The relative change of transmission  $\Delta J/J$  must be proportional to  $p^2_{(\text{Br}_2)}$  in the case of the thermal effect, to  $p_{(\text{Br}_2)}$  in that of the heterogeneous dissociation-effect and to  $\sqrt{p_{(\text{Br}_2)}}$  in the case of the homogeneous dissociation. Fig. 5 shows the value of the exponent  $\gamma$  in the equation:

$$\Delta J/J = \text{const.} \times [\text{Br}_2]^\gamma \quad (8)$$

as a function of  $p_{(\text{Br}_2)}$ , (for the case of helium as third body). The results are in full agreement with theory.

The validity of formula (2) for the region of homogeneous recombination is thus proved in respect of the dependence of the effect on bromine pressure, light intensity and pressure of the foreign gas. This shows, that the recombination process is described by the simple equation

Formation of  $\text{Br}_3$  or of other complexes does not intervene markedly in the recombination process.

FIG. 3b.—Effects observed in nitrogen,  $p_{(\text{Br}_2)} = 4.5 \text{ mm.}$

#### IV. Calculation of the Recombination-Constants.

Table I. contains the experimental data and the results of the calculation of the constants  $C_1$  of equation (2) for different gases X. Again

as in the case of iodine,<sup>2</sup> the results obtained in  $\text{O}_2$  above 450 mm. and in  $\text{CO}_2$  above 200 mm. indicate that the thermal effect is destroyed at these pressures by convection-currents, as discussed in <sup>6</sup>.

FIG. 4.—Dependence of the effect on light-intensity.

The values of  $C_1$  obtained with bromine are less exact than those obtained with iodine<sup>2</sup> because the effects are considerably smaller. (The extinction-coefficients  $\bar{\alpha}_J$  and  $\bar{\alpha}_I$  being much lower for  $\text{Br}_2$  than for  $\text{I}_2$ .) Considering Table I. we may assume that the  $C_1$  values are correct to about 10 per cent. in the case of He and  $\text{H}_2$ , and to 25 per cent. in that of A. We must, however, mention, that the reproducibility of the results, which was very good with iodine, was not so good with bromine. Sometimes, under apparently identical conditions, we found effects 20-40

<sup>6</sup> E. Rabinowitch, *Z. physik. Chemie (B)*, 1936.

per cent. smaller than those which were used in the calculation of the tables. It appears as if small traces of some unknown substances are able to catalyse the recombination of bromine atoms. In experiments with iodine we found that practically no dissociation-effect can be observed in mixtures of  $I_2$  with water-vapour. It is therefore possible that traces of moisture are responsible for the smaller effects in bromine also. This is, however, a point requiring special investigation.

The results used in Table I. were those in which the highest effects were observed. After a few experiments giving "too small" effects, we were always able to obtain the higher ones again. This was proved especially in the case of helium, where about 20 sets of measurements gave results in accordance with Table I. Table II. which contains a comparison of the recombination constants for bromine and iodine, confirms the reliability of the bromine values by showing their constant relation to the corresponding values for iodine.

FIG. 5.—Dependence of the effect on bromine-pressure.

TABLE II.—RECOMBINATION-CONSTANTS FOR BROMINE AND IODINE.

X =	H <sub>2</sub> .	He.	CH <sub>4</sub> .	N <sub>2</sub> .	O <sub>2</sub> .	A.	CO <sub>2</sub> .	C <sub>2</sub> H <sub>6</sub> .

$\gamma(\text{Br}) \times 10^3$	2.2	0.82	3.7	2.7	3.4	1.4	5.7	—

The gases are arranged in Table II. in order of their molecular weights, to show that the relation  $C_1(\text{Br})/C_1(\text{I})$  is slightly higher for the light gases H<sub>2</sub> and He, and practically constant for all the heavier ones. This suggests that the *velocity* of the molecules has a somewhat greater influence on their efficiency as third bodies in the case of the recombination of bromine atoms.

The last row of Table II. shows the proportion of the total number of

double collisions  $\text{Br} + \text{Br}$  which are recombining collisions at atmospheric pressure of the gas  $X$  ( $t = 20^\circ \text{C}$ ). The number of double collisions is calculated by the usual kinetic formula, using the reasonable value  $4.5 \text{ \AA}$ . for the collision diameter of two Br atoms. One collision in 1200 is a recombining one in helium, and one in 175 in carbon dioxide.

The order of efficiency of different gases in promoting recombination is the same as in the case of iodine. Monoatomic gases have a smaller effect than the polyatomic ones. The efficiency increases with growing molecular size and intensity of the van der Waals' forces of the colliding molecules.

For the comparison of the values of  $C_1$  given in Table II. with those derived by Jost<sup>7</sup> and Hilferding and Steiner<sup>8</sup> from the kinetics of the bromine-hydrogen reaction we must refer to a separate note.<sup>6</sup>

### V. Effects in Pure Bromine.

As stated above, the effects observed in pure bromine are of thermal origin. It has already been shown (Figs. 4 and 5) that the dependence of the effect in pure  $\text{Br}_2$  on light intensity and bromine concentration is in accordance with this theory. We will now show the same for the *absolute magnitude* of the effects.

From formula (1) we derive

$$\frac{\Delta_{\text{therm.}}}{Q} = - \frac{3}{32\kappa_{(\text{Br}_2)}T} = 32 \quad . \quad . \quad (10)$$

using the values  $T = 293^\circ \text{ abs.}$  and  $\kappa_{(\text{Br}_2)} = 1.0 \times 10^{-5}$  (for derivation of this value see <sup>1</sup>).

The effects in pure  $\text{Br}_2$  vapour are very large at higher pressures; the calculation of  $\Delta$  and  $Q$  is, however, somewhat complicated, the simple formulæ (5) and (6) being valid only for small absorptions. For the calculation of  $\Delta$  at higher pressures, we determined experimentally the transmission  $J$  as a function of  $p_{(\text{Br}_2)}$ . By differentiating the curve  $J = f(p)$  we obtained the values of  $dJ/d[\text{Br}_2]$  for different pressures, and were thus able to calculate  $\Delta \equiv \frac{\Delta[\text{Br}_2]}{\text{Br}_2}$  from the experimental values of  $\Delta J/J$ .

For calculating  $Q$ , we introduced into (5) a correction (not exceeding 20 per cent.) accounting for the absorption of the  $L$  light between the middle of the vessel and the back wall, using the values of  $\bar{\alpha}_L$  given in Fig. 1 A.

Fig. 6 shows the values of  $\Delta/Q$  calculated from a large number of experiments. Circles refer to measurements made with  $L$  light filtered through  $\text{CuSO}_4$  only (*cf.* Fig. 1), crosses to measurements made with Wratten-filter No. 32 in addition to the  $\text{CuSO}_4$ -filter. Filter 32 cuts off all wave-lengths above the convergency limit of  $\text{Br}_2$  at  $5000 \text{ \AA}$ .; we used it at the beginning of our investigation in order to be sure of the absence of any effects due to *excitation* of  $\text{Br}_2$  molecules. The numerical coefficient in equation (5) is  $3.10$  for the light filtered through filter No. 32.

Fig. 6 shows that the values of  $\Delta/Q$  are practically constant at pressures above 11 mm. The mean value is 35, which is remarkably close to the theoretical value 32 (shown by the thick line). A better agreement cannot be expected on account of the idealisations used in the theoretical treatment. An endless cylindrical vessel  $r = 1 \text{ cm.}$ , was considered in

<sup>7</sup> W. Jost, *Z. physik. Chemie (B)*, 1929, **3**, 83, 95.

<sup>8</sup> K. Hilferding, W. Steiner, *ibid.*, 1935, **30**, 399.

the derivation of (1), whereas the actual experiments were made partly in a cylindrical vessel  $r = 1$  cm.,  $d = 10$  cm., partly in a rectangular cell  $2 \times 2 \times 12$  cm.

This result proves the essential correctness of the theory of the thermal effect, especially the assumption that convection can be neglected in calculating the stationary state of the illuminated gas (at least in the case of pure  $\text{Br}_2$  vapour at pressures up to about 20 mm.).

Below  $p(\text{Br}_2) = 11$  mm., the values of  $\Delta/Q$  decrease. We predicted<sup>1</sup> that an effect of this kind must occur: it is due to the transition from the region of homogeneous recombination into that of predominant wall-recombination. The bending of the curve at  $p = 11$  mm. in Fig. 6 has thus the same meaning as the maxima in Figs 2 and 3. The decrease in the thermal effect at pressures below this point is caused by the walls ab-

FIG. 6.—Dependence of the effect in pure bromine on pressure.

sorbing the recombination energy of the atoms. In the extreme case of purely heterogeneous recombination the whole of the dissociation energy is conveyed to the walls. The thermal effect does not, however, disappear completely. This result was also predicted<sup>1</sup> as a consequence of the fact that the light-quanta absorbed are greater than those required for the bare dissociation of  $\text{Br}_2$  into two normal Br atoms. The excess energy is converted partly into the excitation energy of the one Br atom, and partly into kinetic energy of the atoms. With a mean wave-length 4330 Å., this excess energy  $Q'$  is

$$Q' = \frac{6300 - 4330}{6300} Q = 0.31 Q \quad . \quad . \quad . \quad (11)$$

(6300 Å. being the wave-length corresponding to the dissociation energy of  $\text{Br}_2$ ). The corresponding value of  $\Delta/Q$  is  $0.31 \times 32 = 10$ , and Fig. 6 shows that this is, in fact, the value  $\Delta/Q$  approaches at low bromine-pressures.

The number of double collisions which a Br atom suffers on its way to the wall (*i.e.* on a diffusion-path of the order of 1 cm.) under a pressure of 1 mm. can be roughly estimated as being of the order of  $10^5$  (the diffusion-coefficient of Br atoms into Br<sub>2</sub> assumed to be of the order of 0.05). This gives an upper limit for the stability of the metastable  $^2P_{1/2}$  state of Br for collisions with Br<sub>2</sub> molecules.

The curve  $\Delta/Q = f(p)$  shifts towards higher pressures at lower light intensities, in the same way as was found for the curves of the dissociation effect.<sup>2</sup> Fig. 7 shows  $\Delta/Q$  as a function of  $L$  at three different pressures. At sufficiently high  $L$  values, the limiting value 35 is already attained at pressures below 11 mm. At sufficiently low  $L$  values,  $\Delta/Q$  drops below 35 even at a pressure as high as 16.4 mm.

The position of the "transition point" in pure bromine ( $p = 11$  mm.) can be compared with that found in other gases (for instance  $p = 75$  mm.

FIG. 7.—Dependence of the effect in pure bromine on light-intensity.

in CH<sub>4</sub> and CO<sub>2</sub>). It gives an indication of the great velocity of homogeneous recombination of Br-atoms with Br<sub>2</sub> as third body. Unfortunately the position of this point depends not only on the value of  $C_1$ , but (as shown by Figs. 2 and 3) also on the diffusion-coefficient of the atoms (which determines the slope of the ascending part of the curves). All we can say about the value of  $C_1$  for Br<sub>2</sub>, therefore is, that it must be sensibly larger than the corresponding constant for CO<sub>2</sub>—probably not smaller than  $20 \times 10^{-33}$ .

The effects discussed in this section bear a close connection to the so-called "Budde effect"

(increase in pressure of illuminated halogen vapours) which has been the object of a great number of investigations. Most of them have been carried out under conditions which make a theoretical treatment impossible, (inhomogeneous absorption, complicated shape of the vessel, convection-currents, etc.). The experiments discussed above show that, if suitably simple conditions are chosen, this effect is susceptible of simple theoretical discussion and may be used to provide information concerning the mechanism of conversion of light energy into heat, heat transport, and heat exchange with the walls in different gases.

### Summary.

The stationary state of dissociation of illuminated Br<sub>2</sub> vapour

has been measured by an optical method described previously<sup>1, 2, 3</sup>. The thermal effects were practically suppressed by using a sufficiently low bromine pressure. The velocity constants  $C_1$  of the reactions

have been determined for a number of different gases X. (He, A, H<sub>2</sub>, N<sub>2</sub>, O<sub>2</sub>, CH<sub>4</sub> and CO<sub>2</sub>.) The results are given in Table II. The recombination-velocity of Br atoms is 2 to 3 times smaller than that of the iodine atoms with the same "third body" X. One collision Br + Br in 1100 is a recombining one in He at atmospheric pressure, 1 in 175 in CO<sub>2</sub>, etc.

The dependence of the degree of dissociation on light intensity, bromine concentration and pressure of the gas X is in agreement with the theory of the "three body recombination." Br<sub>2</sub> or other complexes play no rôle in the recombination process. Indications were found of some substances (H<sub>2</sub>O ?) catalysing the recombination process.

The effects observed in pure illuminated Br<sub>2</sub>-vapour were also investigated and found to be in quantitative agreement with the theory of the thermal effect.

Our heartiest thanks are due to Prof. F. G. Donnan, F.R.S., for his interest and encouragement in the course of this work, and for the hospitality he gave us in the Sir William Ramsay Laboratories.

## THE HETEROGENEOUS RECOMBINATION AND THE DIFFUSION COEFFICIENTS OF HALOGEN-ATOMS.

BY E. RABINOWITCH AND W. C. WOOD.

*Received 26th March, 1936.*

At sufficiently low pressures the recombination of photochemically produced atoms of Br or I takes place mainly on the walls of the vessel.<sup>1, 2, 3</sup> The resulting stationary distribution of atoms and molecules was discussed in<sup>1</sup> for the simple case of a uniformly illuminated, infinitely long cylindrical vessel of a radius  $R = 1$  cm. The following equation was derived for the mean stationary decrease in the concentration of Hal<sub>2</sub> molecules in the central part of the vessel ( $r = 0.5$  cm.).

$$\Delta[\text{Hal}_2] = \frac{5}{16} \frac{p_{\text{atm.}}(\text{X})N_{\text{h}}}{D_0} \quad (1)$$

$N_{\text{h}}$  is the number of quanta absorbed per sec. in 1 c.c.,  $p_{\text{atm.}}(\text{X})$  the pressure of the gas X (= He, H<sub>2</sub> . . .) filling the vessel and  $D_0$  the coefficient of diffusion of the halogen-atoms into the gas X under atmospheric pressure. The concentration-change  $\Delta[\text{Hal}_2]$  was measured by means of an optical arrangement, described elsewhere.<sup>1, 2</sup>

Formula (1) requires a proportionality of the observed effect with the light intensity and with the pressure of the gas X. These laws in fact hold at sufficiently low pressures, as discussed<sup>2, 3</sup> and shown, for instance, in Fig. 1 for the case of iodine and helium.

<sup>1</sup> E. Rabinowitch, H. L. Lehmann, *Trans. Faraday Soc.*, 1935, **31**, 689.

<sup>2</sup> E. Rabinowitch, W. C. Wood, *J. Chem. Physics*, 1936.

The coefficient  $\frac{\Delta J}{l}$  in (1) is based on the above-mentioned idealisation of the geometrical conditions—the actual reaction vessel was a rectangular one,  $12 \times 2 \times 2$  cm. In observing the thermal effects, which occur under analogous conditions in pure bromine-vapour, we found<sup>3</sup> that the numerical coefficient in a formula derived under the same assumptions was not in error by more than 10 per cent. We may therefore assume the same for the factor  $\frac{\Delta J}{l}$  in (1). The same experiments showed that at sufficiently low pressures the convection-currents play no rôle in conducting to the walls the energy absorbed in the body

FIG. 1.

of the gas. We are therefore entitled to assume that the migration of the atoms to the walls also occurs solely by diffusion. These assumptions permit us to calculate, by equation (1), the diffusion-coefficient  $D_0$  from the experimental values of  $\Delta[\text{Hal}_2]$  found at low pressures of the gas X.

Tables I. and II. contain the experimental data.  $N_{\text{hal}}$  is calculated from  $L$  and  $p[\text{Hal}_2]$  by means of equations (4),<sup>2,3</sup>

$\Delta[\text{Hal}_2]$  from  $\Delta J$  and  $J$  by means of equations (1)<sup>2</sup> and (6).<sup>3</sup> This

gives us the equations above the tables permitting a calculation of  $D_0$  directly from the experimental data. The "most probable"  $D_0$ -values are in most cases those found at the lowest pressures and the smallest light-intensities, because under these circumstances the influence of the homogeneous recombination is smallest.

Table III. gives the comparison of the  $D_0$ -values found for the diffusion of Br and I into different gases X.

The value for  $\text{CO}_2/\text{Br}_2$  is an upper limit only, because 23 mm. is not a sufficiently low pressure for this gas.

The order of magnitude and the relative values of  $D_0$  found for different gases X are all very plausible, thus showing the essential correctness of the mechanism assumed. It is, however, unexpected to find the

<sup>3</sup> E. Rabinowitch, W. C. Wood, *This vol.*, 1936 (preceding paper).

diffusion-coefficients of the Br-atoms about 25 per cent. smaller than those of the I atoms; the inverse relation would appear more likely in view of the relative masses and diameters of the atoms.

Fig. 2 shows the known diffusion-coefficients of monoatomic gases as a function of their position in the periodic system. The values given in Table III. for the I atoms are in agreement with an interpolation for

a monoatomic gas in the fifth period; those found for the Br atoms are rather too small for their position in the fourth period.

The  $D_0$  values of I are more exact than those found for Br, because derived from much larger effects. It is, however, improbable, that all  $\Delta J$ -values used for Br<sub>2</sub> are in error by as much as 50 per cent.

A possible explanation of the experimental results which does not assume that the diffusion-coefficients of bromine-atoms are smaller than those of iodine-atoms is the following. In deriving equation (1),

## 920 DIFFUSION COEFFICIENTS OF HALOGEN-ATOMS

we assumed the concentration of the atoms in the immediate neighbourhood of the walls to be zero. If we put the concentration of atoms at the wall equal to some constant value  $[\text{Br}]_0 \neq 0$ , we obtain, instead of (1), the equation

$$\Delta[\text{Br}_2] - \frac{1}{2}[\text{Br}]_0 = \frac{5}{16} \frac{p_{\text{atm.}}(\text{X})N_{\text{Av}}}{D_0} \quad (2)$$

The same value of  $\Delta[\text{Br}_2]$  now corresponds to a higher value of  $D_0$ .

The recombination of the atoms takes place in the following way: The atoms are adsorbed; they move on the surface of the wall as a two-dimensional gas and recombine by collisions. In the stationary state the concentration of the atoms on the surface must be high enough to make the rate of recombination equal to the rate of production of atoms in the gas. In our experiments  $10^{17}$  atoms were produced per second in the whole vessel (50 c.c.); they had to recombine on a surface of 100 sq. cm., thus requiring a rate of  $10^{15}$  atoms per second per sq. cm.

If we assume the adsorbed atoms to be freely moving about, the total collision-number per second at a concentration  $[\text{Hal}]_{\text{ads.}}$  will be

$$Z_{\text{abs.}} = 2\sqrt{\frac{RT}{M}} [\text{Hal}]_{\text{abs.}}^2 \sigma \quad (3)$$

With  $\sigma$  (the molecular diameter) = 4.5 Å.,  $M = 80$  and  $T = 293^\circ \text{ abs.}$ , we obtain

$$Z = 10^{-3} [\text{Hal}]_{\text{ads.}}^2.$$

The concentration necessary to give  $Z = 10^{15}$  is

$$[\text{Hal}] = 10^9 \text{ atoms/cm.}^2.$$

This is a very small fraction of a complete layer and it is improbable that it gives rise to a vapour pressure of the order of  $1 \times 10^{-4}$  mm. (which

is the partial pressure of the Hal-atoms in the centre of the vessel). It is, however, conceivable that, because of some restriction of the free motion of the atoms on the surface, the stationary concentration of the atoms in the adsorbed phase is much higher than  $10^9$ . The fact that the greater part of the surface is covered with adsorbed  $\text{Hal}_2$  molecules also increases the relative saturation of the surface with atoms. These two causes may result in the vapour pressure of adsorbed Hal-atoms becoming in fact of the same order as their pressure in the centre of the vessel. It is reasonable that this may occur with

Br-atoms although not with I-atoms, because the energy of adsorption of the former is probably much smaller.

We may thus suppose, that whereas the diffusion-coefficients given in Table III. for iodine are correct, the values calculated for bromine may be somewhat too small because of the neglect of the term  $\frac{1}{2}[\text{Br}]_0$  in equation (2).

FIG. 2.

*Note added in Proof.*—Bodenstein and Winter have just published in *Sitzungs-berichte* a paper concerning the  $\text{H}_2 - \text{Cl}_2$  reaction in which they

suggest that the stationary concentration of Cl atoms in an illuminated gas may be practically uniform throughout the vessel (instead of dropping to zero near the surface of the walls). This result is obviously in agreement with the idea we here put forward; it is reasonable to expect adsorbed Cl atoms to have a vapour pressure even higher than that of the adsorbed Br atoms. We do not, however, agree with Bodenstein and Winter in deducing that the "accommodation coefficient" of Cl atoms *must* be much less than unity. The important factor is the equilibrium-concentration of the atoms in the gas phase which may differ from zero, even if every atom striking the walls becomes adsorbed, so long as the velocity of desorption is sufficiently high.

### Summary.

The diffusion-coefficients of the free atoms Br and I into different gases (He, A, N<sub>2</sub>, H<sub>2</sub>, O<sub>2</sub>, CH<sub>4</sub>, CO<sub>2</sub>) are calculated from measurements of the stationary dissociation of illuminated halogen vapours at low pressures.

## THE MECHANISM OF THE CATALYTIC EXCHANGE REACTION BETWEEN DEUTERIUM AND WATER.

BY ADALBERT FARKAS.

*Received 23rd March, 1936.*

The catalytic exchange of hydrogen and deuterium atoms between liquid water and heavy hydrogen,  $\text{HD} + \text{H}_2\text{O} \rightleftharpoons \text{HDO} + \text{H}_2$ , was discovered<sup>1</sup> and fully investigated by Horiuti and Polanyi.<sup>2</sup> According to these authors this reaction involves the ionisation of the hydrogen or deuterium molecules on the catalyst (Pd, Pt or Ni).

The subject of the present paper is the investigation of the catalytic exchange reaction in the gaseous phase on a hot platinum wire.<sup>3</sup>

### 1. Experimental.

The experimental arrangement was similar to that used in the investigation of the catalytic interaction of deuterium and ammonia.<sup>4</sup> A platinum wire (50 cm. long and 0.1 mm. in diameter) mounted in the

<sup>1</sup> J. Horiuti and M. Polanyi, *Nature*, 1933, **132**, 819.

<sup>2</sup> J. Horiuti and M. Polanyi, *Mem. Proc. Manchester Lit. Phil. Soc.*, 1934, **78**, 47.

<sup>3</sup> For an application of this reaction for a method of analysis of heavy water, see A. Farkas, *Trans. Faraday Soc.*, 1936, **32**, 413.

<sup>4</sup> Cf. A. Farkas, *ibid.*, 416.

reaction tube as shown in Fig. 1 was used as catalyst, its temperature being regulated in the usual way by electric heating (Series I.) (resistance of the wire at 15° C. 35.4 ohms) or by heating the whole reaction vessel in a small electric furnace (Series II.). Whilst the two methods give concordant results so far as the progress of the reaction with time and its dependence on pressure are concerned, the dependence of the reaction rate on temperature was more accurately determined by the latter method since then every possibility of a non-uniform temperature distribution (due to end-losses and other causes<sup>5</sup>) is excluded. If not otherwise stated the experiments were carried out by this method. About 1 c.c. of water was placed either in the U-tube (see Fig. 1) or at the bottom of the reaction tube which protruded from the furnace and was kept at constant temperature. Thus the reaction vessel always contained the vapour corresponding to the actual temperature of the water.

FIG. 1.

The experiments were carried out as follows: an amount (usually 15 mm. Hg) of heavy hydrogen (60-100 per cent. D) was added to the water vapour present in the reaction vessel, the filament or the whole vessel heated to the given temperature; from time to time small samples of gas were withdrawn from the tube by means of the capillary lock and the D-content analysed by the micro-conductivity method.<sup>6</sup> In all experi-

ments care was taken to ensure a complete mixing of the gases, *i.e.*, to avoid any differences in the D-content of the hydrogen in the vessel and in that of the hydrogen near the lock, and also to avoid any inhibition of the exchange reaction by lack of a sufficient rate of diffusion of the water vapour to and from the liquid water. Since both liquid water and vapour were always present in very large excess the equilibrium in the exchange reaction was established when practically all the deuterium has disappeared from the heavy hydrogen originally added.

		Mean 0.00895

The catalytic activity of the platinum wire was quite reproducible in a series of experiments carried out during the same day, but changed somewhat in the course of a few weeks. Thus care was taken to ascertain that no change had taken place in the activity of the catalyst when, *e.g.*, the dependence of the reaction rate on temperature or pressure was being investigated.

To obtain some information about the state of the hydrogen in the adsorbed layer, in addition to the exchange reaction, the conversion of *parahydrogen* and *orthodeuterium* was investigated in a way similar to that employed in the catalytic interaction of deuterium and ammonia. This proved to be an excellent tool in investigating the surface properties of the catalyst.

## 2. Dependence of the Reaction Rate on Temperature.

The progress of the exchange reaction with time is shown in Table I. at 236°. It will be noted that the progress of the exchange reaction is well represented by the expression

$$(D) = (D_0)e^{-kt}$$

(D) and ( $D_0$ ) denoting the percentage of D contained in the heavy hydrogen at time  $t$ , and  $t = 0$  respectively), as shown by the constancy of  $k$ .

FIG. 2.

FIG. 3.

Fig. 2 shows the progress of the exchange reaction in a mixture similar to that above in the temperature region 252–410° C.,  $\log D/D_0$  being plotted against time. The temperature 410° C. was obtained by heating the wire electrically, while the reaction vessel itself was kept at 330° C.

In fig. 3 similar lines are shown for the rate of the conversion of  $p\text{-H}_2$ , in the presence of water vapour,  $\log u/u_0$  being plotted against  $t$  ( $u$  =

TABLE II.

(Expt. No. 20. 13 mm.  $o\text{-D}_2$  + 12 mm.  $\text{H}_2\text{O}$ . 327° K.)

Time in Minutes.	$\Omega$ in ohms.	$\Delta\Omega$ in ohms.	Per Cent. D.	Per Cent. $o\text{-D}_2$ in Excess (Relative).
0	13.6	2.54	100	100
3	12.3	1.30	87.5	66
6	11.5	0.72	80.5	43

42	7.6	—	50.0	—
60	6.3	—	41.0	—

excess concentr. of  $p\text{-H}_2$ ). It will be seen that at the same pressure and temperature the *para*hydrogen conversion proceeds about 8–10 times more quickly than the exchange.

Similar results were found if the vessel was kept cold and only the platinum wire was heated electrically. One experiment prob-

ably deserves mentioning in which the *ortho-para*-hydrogen conversion and the exchange reactions are investigated simultaneously in the same gas mixture.<sup>4</sup> In this experiment 13 mm. *ortho*- $\text{D}_2$  were added to 12 mm. of water vapour. The resistance value of this *o*- $\text{D}_2$  as determined according to the microthermoconductivity method is 2.54 ohms higher than that of normal  $\text{D}_2$ , into which it can be reconverted by passing it over a hot nickel filament.<sup>5</sup> Thus the resistance value of each sample withdrawn from the reaction tube was determined, first directly, then after having passed the

nickel filament: the latter value giving the percentage D, the difference between the former and the latter ( $\Delta\Omega$ ) the amount of *ortho*-D<sub>2</sub> in excess relative to normal D<sub>2</sub>. Table II. shows the results obtained. The figures listed in column 2 under heading  $\Omega$  represent the additional resistance value of the sample compared with normal H<sub>2</sub>.

In evaluating the figures listed in column 3 one had to take into account that with the percentage of D the percentage of the molecules D<sub>2</sub> also decreases. Since per cent. D<sub>2</sub> = (per cent. D)<sup>2</sup>/100, the figures in column 5 were obtained from

$$\frac{\Delta\Omega \times 100}{2.54 \times \text{per cent. D}_2} \times 100.$$

The actual per cent. *o*-D<sub>2</sub> is obtained by adding one-third of these figures to 66 per cent. which is the percentage of *o*-D<sub>2</sub> in normal deuteriums. From this table it is evident that whereas the *ortho*-D<sub>2</sub> content has decreased in 5 minutes to half of its original value the D-content decreases by the same amount in 42 minutes, *i.e.* the ratio of the velocities for these two reactions is again 8:1.

In a third series (the catalyst having slightly higher activity than in experiments shown in Fig. 2) the rate of the *parahydrogen* conversion was investigated in the absence of water vapour the U-tube containing the water being kept at the temperature of liquid air. The results obtained are summarised in Table III. together with the data represented graphically in Figs. 2 and 3, the reaction velocity being characterised by the half-life time  $\tau = \ln_2/k$ . The activation energies listed in column 4 were calculated in the usual way according to Arrhenius' formula.

It is evident that in the presence of water vapour the *parahydrogen* conversion appears to be inhibited and its energy of activation considerably increased.

### 3. Dependence of the Reaction Rate on Pressure.

Both the rate of the exchange reaction and the rate of the *parahydrogen* conversion have been investigated in respect to their dependence on the water vapour pressure and hydrogen or deuterium pressure. Some typical results are summarised in Tables IV. to VII.

These results indicate: The absolute rate of the exchange reaction (*i.e.*, the number of D-atoms exchanged) being proportional to the expression pressure/ $\tau$  (*cf.* column 4, Tables V. and VII.) increases somewhat less than linearly with increasing deuterium pressure but is practically independent of the water pressure. (The slight decrease in velocity with decreasing H<sub>2</sub>O pressure might be due to lack of sufficient speed of diffusion between the reaction vessel itself and the U-tube containing the liquid

water.) On the other hand, the absolute rate of the *parahydrogen* conversion is proportional to the *parahydrogen* pressure, but is strongly inhibited by the presence of water vapour. The inhibition is the more marked the lower the temperature, *e.g.*, at  $140^\circ C$ . 5 mm. of  $H_2O$  is enough to cut down the velocity of the conversion to nearly one quarter. This inhibition by water is reversible, *i.e.*, the original activity is recovered as soon as the water is removed (*cf.* Table VI.).

#### 4. Dependence of the Reaction Rate on the Treatment of the Catalyst.

In the experiments so far described the catalyst was not specially treated, and it was found that in the temperature region investigated the activity for the conversion reaction in absence and presence of water and for the exchange reaction was fairly reproducible.

In the following experiments the activity of the platinum wire was measured by the catalysis of the *parahydrogen* conversion in the absence of water vapour (U-tube kept at liquid air temperature, *cf.* Fig. 1). It was found that by glowing the wire *in vacuo* its activity was increased manifold, and water vapour had an extremely strong poisoning effect apart from its reversible inhibition already described (*cf.* Table VI.). On the other hand, addition of air did not influence the activity.

The wire in its active form caused a considerable  $p\text{-H}_2$  conversion even at lower temperatures. The rate of the conversion was again not altered by bringing the wire into contact with a few millimetres of air<sup>7</sup> but was cut down to less than a tenth by adding and removing 0.1 mm. of water vapour (*cf.* Table IX.).

The highly active form of the wire could be also obtained by heating the wire in hydrogen to temperatures above 300° C. as shown by the following experiment. After the wire has been in contact with  $\text{H}_2\text{O}$  vapour the conversion was measured at 238° C. and a half-life of 2.7 mins. The reaction proceeded strictly according to

The results are listed in Table X.

Since in the last experiment the water was added by "warming" the U-tube with the water (or rather ice) from liquid air temperatures to  $-55^\circ C$ . any possibility of the wire being poisoned by impurities such as

Adsorption (in arbitrary units) on  $P_t$ .

FIG. 5.

at room temperatures on the active wire from the speed in the presence of 4.5 mm. water vapour.

The data of Tables III. and X. are shown graphically on Fig. 4, the logarithms of the half-life times being plotted in the usual way against the reciprocal absolute temperature. It will be noticed that though the

absolute velocities vary in the two sets by a factor of 100 the corresponding lines are more or less parallel as is also indicated by the activation energies.

For the sake of comparison one run of the exchange reaction was also made on the wire in its most active form. At 204° C. and 12 mm. H<sub>2</sub>O + 24 mm. deuterium (87 per cent. D) the half-life was found to be 45 minutes (point A' in Fig. 4), i.e., the exchange was proceeding about 10 times more quickly than in the experiments listed in Table III.

### 5. Exchange Reaction with Liquid Water.

In two additional experiments carried out at 20° C. the rate of the *ortho-para* conversion was compared with that of the exchange reaction involving liquid water according to the same technique as described on page 924.

In one case the exchange reaction between 80 per cent. D<sub>2</sub>O (containing N/5 sodium hydroxide) and *parahydrogen* (20 mm.) was investigated, platinum black being used as catalyst. In the other case a suspension of *B. coli* \* in ordinary water was brought into contact with *o*-D<sub>2</sub> and the enzymatic catalysis of the exchange reaction was followed up. The results listed in Tables XI. and XII. in the last column again indicate the relative percentage of the *p*-H<sub>2</sub> or *o*-D<sub>2</sub> in excess in the same sense as in Table II. With platinum as catalyst the conversion proceeds definitely more slowly, whereas with the enzyme catalyst the conversion is practically negligible when compared with the exchange reaction. This is a remarkable fact since in the vapour phase reaction it was found that the *para-ortho* conversion was the quicker process. This behaviour immediately indicates that in the two systems two different mechanisms are responsible for the exchange reaction.

### 6. Discussion.

The dependence of the conversion on pressure gives information as to the concentration of water and deuterium on the surface. Since the inhibition of the *parahydrogen* conversion by water vapour is completely reversible it is most probably due to the surface of the catalyst being covered by an adsorption layer of water. The amount of water covering the surface is then proportional to the inhibition effect. On the other hand, the concentration of the hydrogen in the adsorption layer will be proportional to the absolute rate of conversion or to the expression "pressure/half-life time" listed in Tables V. and VII., column 4. The adsorption isotherms so obtained are shown in Fig. 4 for temperatures

\* The author is very much indebted to Dr. J. Yudkin for the trouble he has taken in preparing the *B. coli* culture.

round 230° C., the concentration in the adsorption layer being given in arbitrary units. It is evident that whereas the curve for H<sub>2</sub>O is characteristic for strong adsorption that for hydrogen indicates weak adsorption, the concentration in the adsorption layer being nearly proportional to the pressure. Qualitatively the same conclusion can be drawn from the pressure dependence of the exchange experiments. Again the absolute rate of exchange varies nearly linearly with the deuterium pressure but is not much dependent on the water pressure.

With regard to the energetics of the individual processes involved in the exchange reaction between deuterium and water vapour we may draw conclusions from the activation energies obtained (see Table XIII.). The activation energy for the *para*hydrogen conversion in the absence of water can be attributed to a process involving dissociation of the molecules and probably migration of the atoms.

The difference between the activation energies for the conversion in the presence and absence of water vapour, *i.e.*, 4.4–7.3 K calories, is to be regarded as the heat of adsorption of water on platinum, whereas the apparent energy of activation of the exchange is characteristic for the rate-determining step itself.

TABLE XIII.

	Activation Energy on the	
	Less Active Wire.	More Active Wire.
Exchange reaction . . . . .	13.5	—
<i>p</i> -Conversion in the presence of water . . . .	10.8	13.7
<i>p</i> -Conversion in the absence of water . . . .	—	6.4
<i>p</i> -Conversion on the flashed wire . . . . .	—	5.0

The next question to decide is what is this rate-determining step. It is certainly not the dissociation of hydrogen or deuterium molecules, since it has been found that the *para*conversion proceeds about 10 times, and on the wire in its most active form about 100 times, more quickly than the exchange. That this is not necessarily always so is clearly shown by the exchange experiments involving liquid water.

In the experiments with liquid water on the contrary it was found that the *para-ortho* conversion was the slow process especially with the enzymes of *B. coli* as catalyst, when there was hardly any conversion to be observed at all. Obviously in liquid water the dissociation of the hydrogen molecules is the rate-determining step, and this is immediately followed by the actual exchange reaction proceeding, at such a high speed that the atoms once formed have little or no chance to recombine to normal molecules and thus cause a conversion. This quickness of the exchange reaction becomes understandable if we assume with Horiuti and Polanyi<sup>1, 2</sup> that in the presence of water not atoms but ions are produced, from the hydrogen molecules. Naturally the exchange of hydrogen ions so produced with the hydrogen or deuterium ions of the water will proceed in general more quickly than the discharge of two ions and the subsequent recombination to normal molecules.

On the other hand, in the catalysis of the gaseous exchange reaction the irreversible poisoning of the activated wire by traces of water vapour

suggests itself as the process connected with the rate-governing step in the exchange reaction. This poisoning effect of water is similar to that of  $\text{NH}_3$  found on an iron catalyst.<sup>4</sup> The irreversibility of the poisoning and its removal by heating the wire in hydrogen or glowing *in vacuo* could be attributed to the formation of some kind of a surface oxide or hydroxide which is reduced by hydrogen or decomposed at high temperatures. If the reduction of this surface oxide proceeds quickly enough an exchange reaction is observed, and it is most probable that actually the reduction of this surface compound is the rate-determining step in the exchange reaction. A direct proof for this view could be given by showing that the dependence of the rate of removal of this surface compound on temperature runs parallel with that for the exchange reaction. Such an investigation is planned also in connection with the catalysis of this exchange reaction by iron and copper in comparison with the reduction of iron and copper oxide.

From the results of the present investigation we may construct the following picture of the interaction of water and hydrogen on the surface of platinum. After having flashed the platinum wire its surface is more or less bare. Hydrogen molecules are readily dissociated into atoms on this surface, and the atoms also readily recombine to molecules. If water molecules come into contact with the platinum they are immediately very strongly taken up and form a stable film of hydroxide or oxide covering most of the platinum surface. This film cannot be pumped off. A further amount of water is adsorbed reversibly, covering the areas left bare by the hydroxide film. In the presence of hydrogen and water with increasing temperature, first the reversibly adsorbed water layer is removed, then the hydroxide film begins to interact with hydrogen and is eventually reduced and removed. The formation and reduction of surface hydroxides takes place alternately and when with sufficient speed the catalysis of the exchange of hydrogen and deuterium atoms between the light or heavy water and hydrogen sets in.

### Summary.

The catalytic exchange reaction between deuterium and water vapour

occurring on a platinum wire has been investigated at pressures of 10-70 mm. and in the temperature region 250-410° C. The speed of the exchange reaction has been compared with the *ortho-para* conversion and hydrogen which proceeds about 10 times more quickly.

The pressure dependence of the exchange reaction and conversion reveals that under the experimental conditions water is strongly adsorbed and hydrogen weakly. It has been shown that by glowing the filament *in vacuo* or heating it in hydrogen a very active catalyst is obtained for the *para-ortho* conversion which is, however, irreversibly poisoned by traces of water vapour. This poisoning effect is to be distinguished from a reversible inhibiting effect of the presence of water vapour on the rate of the *para-ortho* conversion.

As apparent energies of activation the following values have been found :

For the exchange reaction	13.5 K cals.
For the conversion reaction in the presence of water	10.8-13.7 K cals.
For the conversion reaction in the absence of water	6.4 K cals.
For the conversion reaction on the activated wire	5.6 K cals.

Most probably the lowest energies of activation are to be connected with the dissociation and migration of hydrogen. It is suggested that the

difference between the energies of activation for the conversion reaction in the presence and absence of water vapour is the heat of adsorption of  $H_2O$  on platinum and the apparent energy of activation for the exchange reaction is characteristic for the rate-determining process itself. It is shown that the rate-determining step in the exchange reaction is not the dissociation of the deuterium molecule. This is in contrast to the mechanism of the exchange reaction involving liquid water catalysed by enzymes or platinum black, when the conversion reaction is relatively slow and the rate depending step for the exchange is the ionisation as shown by Horiuti and Polanyi. It is suggested that in catalysis of the gaseous reaction the reduction of a surface oxide or hydroxide formed by the interaction of water vapour and platinum is the rate governing step.

The author has much pleasure in expressing his appreciation of the interest Professor E. K. Rideal, F.R.S., has shown in this work. He is also indebted to the Imperial Chemical Industries, Ltd., for financial assistance.

## THE SWELLING OF PROTEIN FIBRES. PART V. THE SWELLING OF SINGLE COLLAGEN FIBRE BUNDLES UNDER LOAD.

BY DOROTHY JORDAN LLOYD AND ROBERT HENRY MARRIOTT.

*Received 6th April, 1936.*

*(From the Laboratories of the British Leather Manufacturers' Research Association.)*

The swelling of single collagen fibre bundles teased out of mammalian hides or skins has been described in previous communications (Marriott, 1932<sup>1</sup> and Jordan Lloyd, Marriot and Pleass, 1933).<sup>2</sup> In this earlier work, changes in length and breadth over a range of  $p_H$  from 0 to 14 were followed for fibres both from fresh hide and from hide which had been treated to remove non-collagenous proteins and subsequently dried by extraction with acetone. The fibres were allowed to swell under a light load of about 0.25 g. The fresh and dried fibres show similar behaviour according to the  $p_H$  of the surrounding fluid but the degree of swelling was found to be widely different in the two cases, the fresh fibres swelling more freely than the dried. Fresh fibres and dried fibres differ also in another particular—the collagen fibrils of which they are composed are held together by encircling sheaths of reticular tissue (Kaye, 1929)<sup>3</sup> which, in fibres strongly swollen in acid or alkali, are ruptured, the remains of the non-elastic reticular sheath becoming visible as constricting bands seen at intervals along the swollen and distorted fibres (Kaye and Jordan Lloyd, 1924).<sup>4</sup> The behaviour of the reticular

<sup>1</sup> *Biochem. J.*, 1932, **26**, 46.

<sup>2</sup> *Trans. Faraday Soc.*, 1933, **29**, 554.

<sup>3</sup> *J. Internat. Soc. Leather Trades' Chemists*, 1929, **13**, 73.

<sup>4</sup> *Proc. Roy. Soc., B*, 1924, **96**, 293.

sheath varies with different fibres and under different conditions. It is more readily ruptured in fibres from adult animals than in those from young animals (Jordan Lloyd and Marriott, 1935,<sup>5</sup> Leplat, 1935),<sup>6</sup> and it seems to be more readily ruptured in fibres from fresh hides or skins than in those from dried hides or skins. In support of the latter contention it may be mentioned that fibres from commercial air-dried hides or skins do not show constricting rings when swollen in acid or alkaline solutions, though fibres from similar material which has been treated for some days with a suspension of lime containing fair amounts of sodium sulphide in solution will, after deliming and swelling in acid solutions, show some constricting rings. The rings can also be seen in fibres from acetone-dried material when swelling freely though they disappear if the fibres are put under load (Marriott). Since the acetone-dried fibres swell less under the same conditions than the fresh fibres, it seems clear that the reticular sheaths are less easily torn. In the present work, where it was desired to use the same fibre in a number of experiments, this was obviously an advantage. Fresh fibres after two or three loadings and swellings were found to fray out and become disorganised. Hence only fibres from pieces of ox-hide purified and dried with acetone by the method previously described (Jordan Lloyd, Marriott and Pleass) have been used in the present work.

The fibres used in the experiments were fixed at their lower ends and the upper ends were clipped to a thin wire, to the free end of which a variable load could be applied. Changes in length and breadth for changes in load and for changes in  $p_H$  of the surrounding fluid were measured photographically by the method previously described (Marriott). The behaviour of the fibres under identical conditions varied to some extent. This is doubtless due to structural causes. The fibres were about 0.1 mm. wide, and showed reversible extension of  $1 \pm 0.4$  per cent. for every gram of load. Generally they broke under loads of 7 to 10 g. though a few fibres could carry a load of 13 grams. One gram load is equivalent to a stress of rather less than 200 lbs. per sq. inch. The breaking stress of the fibres is therefore of the order of 1400 to 2000 lbs. per sq. inch.

Experiments with dry fibres showed that their extension under load was approximately half that of the wet fibres. The extension was reversible on removing the load. The breaking stress was rather higher than for wet fibres.

### Experimental.

#### (A) The Elasticity of the Fibres.

Since it was noticed early in the work that no two fibres behave in exactly the same way under varying conditions it was convenient to use the same fibre for a number of experiments. It was therefore important to establish whether the fibres under load behaved like elastic or like plastic bodies. This was rendered all the more important in view of the fact that Chernov (1936)<sup>7</sup> has recently shown that leather under repeated small mechanical stresses shows plastic properties. Although it had previously been shown that repeated swelling and de-swelling of a fibre without load in hydrochloric acid induces a permanent change in its properties, fibres can maintain their elastic properties unimpaired for over thirty loadings

<sup>5</sup> *Proc. Roy. Soc., B*, 1935, 118, 438.

<sup>6</sup> *Collegium*, 1935, 707, 513.

<sup>7</sup> *J. Internat. Soc. Leather Trades' Chemists*, 1936, 20, 121.

under varied experimental conditions. This is illustrated by reference to Fig. 1 which shows the behaviour under load of fibre No. 1 when stretched in water. This occurred at the 1st, 5th, 9th, 16th, 21st, 25th, 29th and 33rd loadings (only 4 of these loadings are shown in Fig. 1). Other intermediate loadings took place in hydrochloric, nitric and acetic acids and sodium and potassium hydroxides. Over the whole range of experiment, length in water for a given load remained the same. Continuous experiment has a more marked effect on width. Width in water for a given load becomes somewhat erratic after about 25 loadings. The extensibility of the fibres is therefore independent of internal changes in structure which lead to an increase in diameter. This is shown even more clearly on repeated loadings in lime water. Fibres No. 5 and No. 6 were stretched in water and in a saturated solution of lime water. In the latter, loading

took place at once and at one day intervals up to 7 days. For the first 6 days the extensibility of the fibres was unchanged although they were gradually increasing in width throughout the whole time.

In all experiments on loading the fibres, initial and final measurements were taken of fibre dimensions without load. Recovery was very rapid and in most cases complete.

The elastic limits of the fibres were therefore not exceeded within the range of the experiments and the elasticity is evidently founded on some very stable fundamental structure.

### (B) Behaviour Under Load at Various $pH$ Values.

When stretched in water, the length of the fibre plotted against the load gives a straight line with most fibres. With a few, stretching is greater in proportion for the light loads. This is due to the dry fibres having become crumpled and part of the gain in length for light loads is due to the straightening of the fibre. The percentage elongation per unit of load varies slightly with the different fibres but is of the order of 1 per cent. per gram (Fibre No. 1). The percentage decrease in width is also uniform and of the order of 0.5 per cent. per gram.

In solutions which do not induce contraction in fibre length (such as  $N/1000$  HCl,  $N/1000$  HNO<sub>3</sub> and  $N/1000$  H<sub>2</sub>SO<sub>4</sub>,  $N/100$  CH<sub>3</sub>COOH,  $2M$  NaNO<sub>3</sub>,  $N/10$  HCl +  $2M$  NaCl, and, in many cases,  $N/20$  Ca(OH)<sub>2</sub>), the elongation of the fibre under load is the same as in water. Although the actual width of the fibre may be very different under the different circumstances, the diminution of width under load is similar (Figs. 2, 4 and 5).

In water and in  $N/10$  HCl +  $2M$  NaCl, (neither of which induces an increase of width) width is a straight line function of load (Fig. 8). In solutions which cause increase of width without contraction in length this simple relation no longer holds, and some loss of water occurs over and above that squeezed out by the stretching of the fibre. This water may have simply diffused freely in between the fibrils, which can always be seen as distinct entities under these conditions. It will be suggested later that the bulk of the water which enters the fibre from these solutions becomes bound to the collagen molecules of the fibrils and is not displaced by a pull along the fibre axis.

FIG. 3.

- " " " KOH.
- △ Fibre 1 in  $N/20$  Ca(OH)<sub>2</sub> (after 15 mins.).
- ★ Fibre 1 in  $N/20$  Ca(OH)<sub>2</sub> (after 48 hrs.).

With solutions which induce contraction in length, however, this contraction is always associated with an increase of width and volume. The gain in volume is brought about by absorption of water due to osmotic forces. Solutions such as  $N/100$  HCl,  $N/100$  HNO<sub>3</sub>,  $N/100$  H<sub>2</sub>SO<sub>4</sub>,  $N$  CH<sub>3</sub>COOH,  $N/20$  NaOH,  $N/20$  KOH all lead to absorption of water under osmotic forces with contraction of length and increase of width. The first effects of loading such water-distended fibres is to squeeze out the osmotic water with a resultant gain in length and loss in width. The fibre elongates rapidly with increasing loads up to about 3 to 4 grams, after which in the case of  $N/20$  NaOH, and  $N/20$  KOH the curve of length to load runs parallel to that found when stretching in water. In acid solutions the fibre becomes more extensible as the  $p_H$  falls. (See Figs. 3 and 4.)

A striking feature of the behaviour of these osmotically distended fibres under load is that while it is comparatively easy to extend the contracted fibre to its original length in water, the width may remain considerably greater than the original width in water. This can be seen with fibres swollen in dilute strong acids and in alkalis (Figs. 3 and 4). It is

particularly striking with acetic acid (Fig. 5). This is also borne out by reference to the  $p_H$ -length and  $p_H$ -width curves for fibres in hydrochloric

acid. A load of 7 grams is sufficient to extend the acid-swollen fibre back to normal length (Fig. 6) but is insufficient to bring it back to normal width (Fig. 7).

### Discussion.

The absorption of water by a collagenous tissue such as a hide or skin has long been recognised in the tanning industry to occur in two different manners. Hides or skins may become distended with water or "plumped" in which case they are turgid and translucent. This occurs in acid or alkaline solutions in the absence of dissolved salts. They may however become swollen with water yet remain flaccid and opaque. This occurs in salt solutions. Microscopical examination shows that the fibres in the former case are glassy and closely packed and pressed together; in the latter the weaving is much looser and the individual fibrils of the fibres can be clearly seen. Marriott has previously pointed out that in the isolated fibre bundles these two types of water absorption can be distinguished. In the present work the distinction is even more clearly marked. "Plumping," which occurs in acid and alkaline solutions and is characterised by a shortening of the fibre, can be reversed by loading the fibre. Swelling which occurs in salt solutions and also is now shown to accompany "plumping" is characterised by an increase in width of the fibre and cannot be reversed by loading the fibre—it can, however, be reversed by washing the fibre thoroughly in water.

It is now possible to differentiate the chemical bases of these two types of water absorption. "Plumping," (which is characteristic of acid solutions, shows a maximum at about  $p_H$  1.7 for acetone-dried fibres and is completely suppressed by the presence of dissolved salts—see Fig. 8), is due to salt formation between the collagen and the acid and the establishment of a Donnan equilibrium. The fibres absorb water and swell, the monovalent strong acids causing more swelling than the divalent (see Fig. 3). Owing to the lateral bindings of the collagen molecules which lie parallel to the fibre axis, the water drawn in under the osmotic forces of the Donnan equilibrium can only be accommodated at the expense of the fibre length, *i.e.*, the water forces the molecules to bulge sideways in the regions between the collateral bindings (Jordan Lloyd, 1932).<sup>6</sup> By pulling out the fibre, the osmotically-held water is forced out. The force required to expel this water is about 7 gram load on a fibre of 1 mm. diameter or approximately 1500 lbs. per sq. inch. The osmotically held water can be regarded as "free," as far as the protein is concerned and the order of the forces required to expel it from the system is less than the order of the forces required to expel the loosely bound water of iso-electric gelatin in equilibrium with water. Jordan Lloyd and Moran (1934)<sup>7</sup> find that 8000 lbs. per sq. inch is required to remove the latter. Osmotically held water leads to a loss in fibre length and gain in fibre width. Loading the fibre restores the length and very largely restores the width.

When acids act on collagen fibres they do not merely produce a Donnan equilibrium, but have two other effects, *viz.* (a) to cause the loaded fibres to lengthen slightly and to develop a slightly greater extensibility (see Fig. 6), and (b) to increase the width over and above that due to osmotic swelling (see Fig. 7). They also weaken the reticular tissue at  $p_H$  values of 1.2 or less, leading to additional swelling (Jordan Lloyd and Kaye and Jordan Lloyd, Pleass and Marriott, also Fig. 7). If the elasticity of the fibres is to be interpreted on Astbury's theory that the

<sup>6</sup> *J.S.C.I.*, 1932, **51**, 141.  
<sup>7</sup> *Koll. Z.*, 1926, **40**, 264.

<sup>8</sup> *Proc. Roy. Soc., A*, 1934, **147**, 382.  
<sup>9</sup> *Biochem. J.*, 1927, **23**, 358.

molecules are to some extent coiled but can be pulled out under load, the action of acids is consistent with the theory that they form salts with the collagen molecules, which ionise to form a diffusible and non-diffusible ion and that, in doing so, they break the salt linkages previously acting as lateral bonds between carboxyl groups of one collagen molecule and an amino group of an adjacent one.

Acids, however, have an additional action strictly similar to that of salts, which may be attributed to a "Hofmeister effect"; this shows itself microscopically as a splitting of the fibre into fine fibrils and, as regards dimensions, as a gain in width without alteration in length. The water absorbed under the "Hofmeister effect" of acids and salts is undoubtedly to be regarded as "bound" water. Acetic acid is strongly differentiated from the strong acids in this respect (Fig. 5). As regards osmotic action, it conforms to the same  $p_H$  standards but, as regards splitting and gain in width, it is in a class by itself.

Probably the well-recognised fact that all acids have an individual as well as general action on fibres, is due to their "Hofmeister effect" as distinguished from their "Donnan effect."

The action of acids as regards both osmotic swelling (Donnan effect) and as regards lyophylic swelling (Hofmeister effect) is without any permanent effect on the elastic properties of the fibre.

The action of alkalies, like that of acids, can be divided into a "Donnan effect" and a "Hofmeister effect."

The "Donnan effect" or plumping shows very definitely in the case of the monacid bases, sodium hydroxide and potassium hydroxide. With both of these there is diminution in length with gain in width. In the case of calcium hydroxide the "Donnan effect" is not always evident, some fibres showing a slight shortening and others apparently, showing none. There is a latent period from  $p_H$  5 (the iso-electric point of collagen) to  $p_H$  11.2 over which there is no "Donnan effect" showing itself as a shortening of the fibre. A splitting or "Hofmeister effect" showing itself as a gain in width starts about  $p_H$  9. This splitting action of the fibre into its constituent fibrils is evident on microscopical examination and is a very conspicuous feature of the action of lime water. As regards the action of alkalies on the reticular sheaths, evidence is somewhat lacking. Kaye<sup>10</sup> has reported that they are not affected by lime but are weakened by sodium sulphide. The absence of any well-defined peak of alkaline swelling for collagen fibres suggests that the reticular tissue is weakened in sodium hydroxide solutions of  $N/10$  strength or thereabouts.

Alkalies of moderate concentration seem to be without effect on the elastic properties of fibres and there is no tendency for the loaded fibres to gain in length in alkaline solutions or to become more extensible.

The action of salts on fibre swelling appears to be purely a "Hofmeister effect." There is much microscopical evidence that salts cause splitting of the fibres into their constituent fibrils with a gain in width. Nitrates show this very clearly. Salts do not cause any noticeable change in fibre length but there appears to be a slight elongation in some cases. Salts ( $2M$   $NaNO_3$ , Fig. 2) have no effect on the elastic properties of the fibres.

<sup>10</sup> *J. Internat. Soc. Leather Trades' Chemists*, 1936, **20**, 223.

### Summary.

1. Collagen fibres have, over a wide range of conditions, elastic properties which appear to be those of the fundamental molecular structure of the fibrils. Wet fibres have about twice the extensibility of dry fibres, namely about 7 per cent. extension at the elastic limit.

2. Collagen fibres can absorb water and swell under two independent sets of forces, those due to (1) the formation of a Donnan equilibrium which is controlled by the  $p_H$  of the system and (2) a Hofmeister effect of dissolved acids, bases or salts, in which each chemical reagent produces its own characteristic effect.

3. It is suggested that the Donnan or  $p_H$  effect is osmotic and leads to an increase of free water in the system while the Hofmeister effect leads to an increase of bound water.

4. The water absorbed under the action of acids or alkalies (Donnan effect) leads to a shortening of the fibre but can readily be removed by loading the fibre. The shortening is accompanied by increase of width which is reversed on loading the fibre.

5. The water absorbed under the action of salts or very dilute acids or alkalies leads to an increase of width without shortening (Hofmeister effect). This increase is not reversed on loading the fibre. Acids and alkalies at concentrations which cause shortening also show this non-reversible gain of width.

6. The order of the forces required to remove the osmotic water from acid swollen fibres is less than that required to remove the loosely bound water from iso-electric water-swollen gelatin.

7. Strong swelling in acid solutions ( $p_H < 1$ ) leads to a tearing of the reticular sheaths round the fibres with a consequent further absorption of water, but apparently with no change in the elastic properties.

## THE ROENTGENOGRAPHIC STUDY OF ZINC AND CADMIUM FILMS DEPOSITED IN THE PRESENCE OF COLLOIDS.

(A PRELIMINARY COMMUNICATION).

BY L. PALATNIK.

*Received 20th January, 1936.*

As is well known, colloids are introduced into the electrolytic bath for the purpose of obtaining bright, finely-grained depositions. We studied by X-rays Zn films deposited in the presence of dextrine, and Cd films deposited in the presence of dextrine, sulphonated castor oil and cereal extracts. The conditions of deposition are given in Table I.

It follows from the work of Glocker and Kaupp,<sup>1</sup> and other workers, that during the electrolytic deposition of Cu, Ag, Cr, Ni and Fe in baths of corresponding compositions (in the absence of colloids) there are formed textures, the degree of perfection and axis of which depend on the conditions of the deposition (current density, electrolyte composition, etc.).

Bozorth's researches<sup>2</sup> have shown that no texture is observed for

<sup>1</sup> Glocker a. Kaupp, *Z. Physik*, 1924, **24**, 121.

<sup>2</sup> Bozorth, *Physical Rev.*, 1925, **26**, 390.

Zn and Cd. It is seen, however, from the X-ray diagrams (Figs. 1-2) that, during the electrolytic deposition of these metals (Zn and Cd) in the presence of above-mentioned colloids, a texture can be observed, although an imperfect one, particularly for Zn. (See diagrams facing p. 869.)

For Zn, the (221) planes tend to lie parallel to the surface. We discovered also that the degree of the orientation of crystals depends on the concentration of colloids in the electrolyte (Figs. 3, 4, 6), as well as on the current density (Figs. 4, 5). We propose to make use of this fact as a method for determining the "effective concentration" of a colloid in the bath. The relative intensity of the Debye-gram lines for Zn and Cd films undergoes a sharp change depending on the concentration of the freshly-prepared colloid (Figs. 3, 4, 6, 8, 9, and 10).

TABLE I.

Composition of Electrolyte.	Current Density	Time of Exposure	Cathode.
<b>1. Deposition of Zinc.</b>

Dextrine : 0, $\frac{1}{2}$ , $\frac{1}{2}$ , 1, 2, 4, 6, 8 and 10 gm			
<b>2. Deposition of Cadmium.</b>			
CdO . . . . . 16 gm.	0.75, 1 amp / dcm <sup>2</sup>	10, 30 minutes	Cu and Fe
KCN . . . . . 200 "			
H <sub>2</sub> O . . . . . 1 litre			
The colloids			
Cereals extracts 0.25, 0.5, 1 gm			
Sulf castor oil 0.1, 0.2, 0.5, 1 "			
Dextrine . . . . . 0.5, 1 "			

As has already been observed during the operation of a bath, there occurs in the course of time a gradual "disappearance" of the colloid. For this reason it seems to be advisable under factory conditions to verify the "effective concentration" of a colloid. The author has obtained a series of X-ray diagrams for Zn and Cd deposited from various concentrations of freshly-prepared colloids (but under the same other conditions of current density, time of electrodeposition, composition of electrolyte, material and treatment of the cathode, etc.), which serve as standards for every control determination of the "effective concentration" of the colloid in the given electrolyte. Thus, the analysis can be accomplished within from 3 to 5 hours.

The Debye-grams were taken with a plane sample, at an angle of 47° to the original beam (a different angle may be used so long as the same angle is always maintained for the determinations) of the Fe or Cr radiation (the anti-cathode may also vary).

We also noticed an increase in the brightness of films, with the degree of orientation of crystallites. This very phenomenon has recently been observed by Wood<sup>2</sup> for Cr and Ni electrodeposited in corresponding baths (not containing colloids).

<sup>2</sup> Wood, *Trans. Faraday Soc.*, 1935, 31, 1248.

Thus we can now take it for certain that, in the case of Cd and Zn, colloids bring about the formation of a texture, *i.e.*, they promote the growth of crystals in a single crystallographic direction, *viz.*, perpendicular to the surface of the cathode (see also <sup>4</sup>).

## THE COLOUR AND OPACITY OF EMULSIONS.

BY JAMES FREDERICK MORSE.

*Received 30th March, 1936.*

The mixing of an aqueous liquid with an oily liquid usually results in a creamy emulsion, due to the differing refractive indices and optical dispersive powers of the two phases. When the two liquids have the same value for refractive index and optical dispersive power a transparent emulsion is obtained. Holmes and Cameron <sup>1</sup> have shown that if emulsions be made of two liquids of equal refractive indices (ensuring transparency) but widely different optical dispersive powers, the system is comparable to a multitude of lenses or prisms with consequent prismatic colour effects. The optical properties of these chromatic emulsions have been described by Sogani.<sup>2</sup>

Some experiments <sup>3</sup> have been carried out on dilute castor oil emulsions with polarised light, and Teorell <sup>4</sup> using dilute ultramicroscopic emulsions of mastic investigated their optical properties together with those of sols of gelatin and ferric hydroxide.

Bechhold and Hebler <sup>5</sup> in their nephelometric investigation of graded suspensions of barium sulphate found that the light scattered increased as the particle size decreased from  $2.5\ \mu$  to  $800\ \mu\mu$ , but thereafter decreased.

No work appears to have been reported concerning the opacity of emulsions as influenced by the concentration and degree of dispersion of the internal phase and the subsequent effect on the final colour of the emulsion should one of the phases be coloured.

Several systems of colour measurement are in vogue for dealing with transparent and opaque material. Semi-opaque and translucent systems present difficulties, since the former are insufficiently opaque to be gauged by reflected light and the latter scatter too much light to permit measurement by the transmission method. Visual and photo-electric methods of colour recording are available. Of the former that of Lovibond is the best known, but for more scientific data a form of spectrophotometer is usually employed.

<sup>1</sup> *J. Am. Chem. Soc.*, 1922, 44, 71.

<sup>2</sup> *Phil. Mag.*, 1926, 1, 321; *Proc. Ind. Assocn. Cult. Sci.*, 1920-21, 6, 134.

<sup>3</sup> D. S. Subbaramaiya, *Proc. Ind. Acad. Sci.*, 1935, 1A, 709; R. S. Krishnan, *ibid.*, 1935, 1A, 717.

<sup>4</sup> *Kolloid. Z.*, 1930, 53, 322; 1931, 54, 58; 1931, 54, 150.

<sup>5</sup> *Ibid.*, 1922, 31, 70.

The apparatus of Toussaint<sup>6</sup> was the pioneer of commercial photo-electric colorimeters. Designed primarily for the textile trade the colour of opaque and transparent material may be measured. Bolton and Williams<sup>7</sup> utilising this method for oils introduced an aqueous copper sulphate filter with the object of removing infra-red rays to which photo-electric cells, in general, are very sensitive.

The principle underlying these methods is to direct a beam of light of known wave-length on (in the case of opaque material), or through (in the case of transparent liquids) the sample to be examined. The reflection or transmission is then recorded by a galvanometer connected to the photo-electric cell on which the light falls after leaving the sample. Immediately after or before the above reading is taken, the light is di-

FIG. 1 (A).

FIG. 1 (B).

parent liquids. Six readings are usually taken, using filters approximately to traverse the visual spectrum.

The following Wratten filters were employed in the apparatus to be described :—

49 (C4), 75, 62, 73, 72, 70.

A spectrographic examination of the filters revealed that the predominant wave-lengths transmitted were :—

4200Å, 4600Å, 5000Å, 5400Å, 5700Å, 6400Å respectively.

The apparatus constructed in these laboratories is shown diagrammatically in Fig. 1, arranged for colour measurement of transparent liquids (A), and as employed for opaque samples (B).

The light from the projection lamp A passes through the iris diaphragm B and the copper sulphate filter C contained in a Soyka flask. The light is then directed by the condenser D through the filters E to the standard and samples F which the slide G allows to be rapidly brought into the beam of light. The condenser H collects the light when it is directed upon the Weston photonic photo-electric cell I. The current so generated is measured directly to 0.05 micro-ampere and by estimation to 0.01 micro-ampere by a Cambridge Metre. Liquids are contained in 1-inch Lovibond

<sup>6</sup> See L. Blin Desbleds "Exact Colour Matching and Specifying" (Paris).

<sup>7</sup> *Analyst*, 1935, 60, 447.

rected upon a standard and from this reading the percentage reflection, or transmission of the sample is calculated. In the case of opaque material the standard may be a block of pure calcium sulphate or magnesium carbonate, while water or colourless oil, as occasion demands, serves as a standard for trans-

cells and opaque material in ebonite cells 1 cm. deep. The condenser H is not necessary for measurements with transmitted light but its inclusion enables the instrument to be used immediately for opaque or transparent samples.

From the readings obtained the percentage (based on the standard 100 per cent.) transmission or reflection is calculated for the predominating wave-length of light transmitted by each of the six filters. Fig. 2 records the colour curves of 0.1 per cent. Oil Orange and 0.1 per cent. Sudan III. in liquid paraffin, a 1-inch Lovibond cell being used and liquid paraffin as standard. An average of the six percentage transmissions gives the "mean tone" which may be regarded as a measure of brightness irrespective of the actual hue. If such a coloured oil formed the dispersed phase of an emulsion the colour of the emulsion would depend upon the concentration of the oil and the degree of dispersion; the colouring matter determines the hue and the opacity of the emulsion determines the tone.

Fig. 3 shows the effect of dispersion on the tone of a

coloured emulsion. It will be seen that the tone has increased with the degree of dispersion and consequently the opacity. To compare actual increases in the "brightness" of colours it is convenient to calculate the mean tone (as a percentage of the white standard) and plot this against the average globule size. Fig. 4 shows the relation.

It is obvious that irrespective of (a) the particular colour employed, (b) in which phase it is present, and (c) the type of emulsion, (O/W, W/O), the final colour effect will depend on the opacity of the emulsion. This in turn will depend on the refractive indices and optical dispersive powers of

FIG. 2.

the two phases and on the concentration and globule size of the internal phase.

With the refractive indices and optical dispersive powers maintained

10% Liquid Paraffin in Water.  
Oil containing 0.1% Sudan III.

FIG. 3.

FIG. 4.

constant, the effect of the concentration and the globule size of the dispersed phase was now examined. Emulsions of liquid paraffin were employed as a colourless oil is necessary. The emulsions were prepared by mixing predetermined proportions of fairly low viscosity paraffin ("slab oil") with an aqueous gum solution containing 1.5 grams gum tragacanth and 8.5 grams gum acacia per 100 c.c. Varying degrees of dispersion were obtained as follows:—

(1) Handshaking: 40 c.c. emulsion were shaken 50 times in a 120 c.c. bottle. After determining the globule size and opacity the same emulsion was—

(2) Shaken 50 times in the same bottle, but with the addition of 25 glass beads, 7.5 mm. diameter. After examination the same emulsion was passed through—

(3) "Empire" cream machine whereby the emulsion is forced through a fine orifice partially blocked by a wire. To obtain

a range of dispersions the emulsion was treated up to 10 times in this machine.

(4) The excellently constructed "Impulsor" laboratory homogeniser permitted emulsions of high dispersion. Photomicrographs employing a modified Hvidberg\* technique—showed remarkably uniform and highly dispersed emulsions obtained with this machine in which 20 c.c. of mixture were sufficient.

The globule size was determined by means of an eyepiece micrometer, standardised against a 1/100 mm. ruling, and direct examination with a Leitz No. 3 objective for the coarser emulsions and a No. 7 objective for the homogenised emulsions.

Emulsions were prepared of 5, 10, 15, 20 and 50 per cent. concentrations of liquid paraffin in gum solution, varying dispersions being obtained by the methods described above. After recording the globule size the opacity, as measured by the reflection (calculated to a percentage of the white standard - calcium sulphate), of the emulsion was determined in a 1 cm. deep black cell. Fig. 5 gives the "colour" curves of 10 per cent. emulsions of varying grain sizes. The average of the six values gives the mean tone and in Fig. 6, these mean tones are plotted as percentage "opacities" against globule size for a range of oil concentrations. During

the recording of a large number of these "opacities," it was found that the "mean tone" closely corresponded to the percentage reflection using the yellow filter, wave-length 5400Å, and in subsequent work this figure was taken as the opacity.

It will be seen from Fig. 6 that a layer of emulsion 1 cm. deep will appear equally opaque and white irrespective of the fact that the dispersed phase

FIG. 5.

\* *Kolloid. Z.*, 1935, 72, 274.

may be 5 per cent. or 50 per cent., provided that the globule size is in the neighbourhood of  $1\ \mu$ .

Maintaining a uniform globule size the effect of concentration was investigated. Emulsions of 25 per cent. liquid paraffin were prepared.

FIG. 6.

and the final homogenisation. When a 25 per cent. emulsion of sufficiently uniform globule size had been obtained, it was diluted to give

FIG. 7.

a series of concentrations, the opacity of each one being recorded. Fig. 7 shows such a series at various globule sizes. Some discrepancy in opacity at the larger globule sizes is evident between this series and those in Fig. 6, no doubt due to the less uniform emulsions of the latter. At dilute concentrations the effect of globule size is most marked and any irregularities have a pronounced effect.

Figs. 6 and 7 give a guide to the relative opacities to be expected with emulsions in which the phases have optical properties corresponding to those of liquid paraffin and aqueous gum solution. If a coloured solute be present in one of the phases of the emulsion, the resulting colour of the emulsion is a function of the opacity.

### Summary.

(1) An investigation has been made relating to the opacity of emulsions as influenced by the factors of concentration and grain-size of the internal phase.

(2) A photo-electric photo-colorimeter and six spectrum filters were employed to determine (a) the effect of grain-size on the tone of a coloured emulsion, (b) the opacity of emulsions of varying grain-size and volume-ratio.

(3) Emulsions of very fine grain, about  $1\mu$  diameter, contained in a 1 cm. deep cell, exhibit equal opacities when the concentration ranges from 5 per cent. and upwards. Added oil-soluble or water-soluble colouring matter does not affect this result.

Grateful acknowledgment is made to Dr. William Clayton for his deep interest throughout this investigation, and to Colonel E. A. Rose of the Improved Emulsification Process Company Limited for the loan of the "Impulsor" laboratory homogeniser without which the production of small quantities of the fine grain emulsions would not have been possible.

## IONIC EXCHANGE AND SORPTION OF GASES BY CHABASITE.

BY E. RABINOWITCH and W. C. WOOD.

*Received 20th February, 1936.*

Chabasite crystals have a skeleton lattice formed by the ions  $\text{Si}^{4+}$ ,  $\text{Al}^{3+}$  and  $\text{O}^{2-}$ . The hollows are occupied by positive ions, chiefly  $\text{Ca}^{2+}$ , and by neutral molecules, usually  $\text{H}_2\text{O}$ . Calcium can be exchanged for other divalent or monovalent ions, water for other molecules of appropriate size.

In a previous paper<sup>1</sup> several dehydrated chabasite samples from different localities, were found to possess about the same power of sorption; one, however—that from Richmond (Victoria)—sorbed three or four times less gas than all the others. Data available in Dölter's *Handbuch der Mineralogie* indicate that this chabasite is abundant in alkali ions, and we thought that this might be the reason of its low sorptive power. We therefore investigated the sorption by a number of chabasites in which calcium was exchanged for a series of different ions.

<sup>1</sup> E. Rabinowitch, *Z. physik. Chemie*, 1932 (B), 16, 43, further quoted as "Dölter's"

### Experimental.

**1. Preparation of the Samples.**—The purest crystals of chabasite from Rübesdorfel (Czechoslovakia) were washed in  $\text{CCl}_4$  and ground. Portions of 3 gm. were mixed with 30 c.c. of 10 per cent. chloride solutions, and kept at about  $100^\circ \text{C}$ . for 200 hours, during which the solutions were replaced three times. The samples were then left exposed to the air for several days to allow them to acquire their "natural" water content, and analysed.

**2. Analyses of the Samples.**—We investigated samples treated with  $\text{NaCl}$ ,  $\text{KCl}$ ,  $\text{MgCl}_2$ ,  $\text{CdCl}_2$ ,  $\text{CaCl}_2$ ,  $\text{SrCl}_2$ ,  $\text{BaCl}_2$ , and  $\text{LaCl}_3$ . Approximately 0.5 g. were dissolved in 400 c.c. of conc.  $\text{HCl}$  for the separation of  $\text{SiO}_2$ . The treatment of the deposits with  $\text{H}_2\text{SO}_4$  and  $\text{HF}$  (for the separation of  $\text{SiO}_2$  from traces of barium, calcium, etc.), was omitted; the  $\text{SiO}_2$  values given in the following tables may therefore be a little too high.

A complete ionic exchange took place with  $\text{NaCl}$ ,  $\text{KCl}$  and  $\text{BaCl}_2$ , and a partial one with  $\text{SrCl}_2$  and  $\text{CdCl}_2$ . The  $\text{MgCl}_2$  sample contained only 2.3 per cent.  $\text{MgO}$ ; that treated with  $\text{LaCl}_3$  was practically identical

with the original material (a spectroscopic test revealed the presence of about 1 per cent. of lanthanum). The sample treated with  $\text{CaCl}_2$  was also unchanged; the small quantities of  $\text{Na}_2\text{O}$  and  $\text{K}_2\text{O}$  present in the original mineral were not exchanged for  $\text{CaO}$ . These three preparations were discarded for the sorption experiments. The composition of the other five, together with that of the original material (which is a typical Ca chabasite), is given in Tables I. and II. Table II. shows that the molecular composition of the samples can be represented by the formula:—

X standing for one mol. of bivalent or two mols. of monovalent ions. The ionic exchange takes place in a strictly stoichiometric way.

The water content of all the substituted chabasites is about the same, that of the potassium chabasite being, however, somewhat lower.<sup>2</sup>

**3. Sorption Experiments.**—For each experiment 1 g. chabasite powder was placed in the hard glass tube F (Fig. 1), covered with asbestos

wool to prevent sputtering and then heated to  $500^\circ$  for 2 hours, under constant pumping by a mercury pump. Traps D and E were immersed in liquid air (in experiments with  $\text{CO}_2$  and  $\text{C}_2\text{H}_6$  in solid carbon dioxide) to protect the chabasite from mercury and grease vapours. Gases were introduced in small portions from the container A, into the tube F, the quantity introduced being determined by the drop of pressure in A (manometer B), the resulting pressure in F by the manometer C. The quantity of

<sup>2</sup> E. Gruner (*Z. anorgan. Chemie* (1933), 211, 385) assumes  $7\text{H}_2\text{O}$  in the calcium chabasite and  $5\text{H}_2\text{O}$  in the alkaline chabasites.

gas sorbed was calculated by subtracting from the total quantity admitted into F the small quantity filling the tubing FD. The same sample was used for experiments with all gases, as it was shown that repeated heating had no effect on its sorbing capacity.

### Experimental Results.

A set of successive pressure measurements with increasing gas quantities served to determine a sorption isothermal. In accordance with

Sorption of:	$R$ (c.c./gm.).	$R$ and $W$ (c.c./gm.).
(1) $N_2$ (at $-190^\circ \text{C.}$ , $p = 400 \text{ mm.}$ ) .	170	163
(2) $H_2$ (same conditions) .	130	130
(3) $\text{CO}_2$ , ( $p = 100 \text{ mm.}$ , $t = +20^\circ \text{C.}$ )	110	115

previous experience, the isothermals obtained with  $H_2$  and  $N_2$  were well reproducible; it was, however, difficult to reproduce measurements with  $\text{CO}_2$  to more than 10 per cent.

and in the case of  $\text{C}_3\text{H}_8$  deviations of 50 per cent. were quite possible. This is due to the great velocity with which the equilibrium is reached in the case of  $H_2$  and  $N_2$ , the pressure becoming constant a few seconds after

the introduction of the gas. With  $\text{CO}_2$ , one has to wait for an hour or more (at the higher pressures), and a day or more is necessary with  $\text{C}_3\text{H}_8$ . The results obtained with  $\text{C}_3\text{H}_8$  (Fig. 5), are therefore not very reliable. The sorption values obtained with the natural calcium chabasite were practically identical with those found in Paper I.

The changes in the sorption power caused by ionic exchange are reversible. By treating a sample of potassium chabasite with a solution of  $\text{CaCl}_2$ , we recovered a calcium chabasite which sorption isothermals were practically identical

with those of the original mineral. The results of the sorption measurements are given in Figs. 2, 3, 4 and 5.<sup>3</sup>

<sup>3</sup> The numerical data underlying Figs. 2-5 can be found in the dissertation by W. C. Wood, University of Göttingen, 1934.

The conclusions which can be drawn from these isothermals are as follows:—

(a) The three *alkaline earth chabasites* have practically identical sorption properties (the differences observed in experiments with  $C_3H_8$  are not certain enough for discussion).

(b) *Cadmium chabasite* isothermals run somewhat below those of the alkaline earth products, indicating a lower sorption energy. It is, however, probable that the saturation values are the same. The unchanged water content supports this assumption.

(c) *Sodium chabasite* is characterised by a very small sorption capacity for *nitrogen*.

$H_2$ ,  $CO_2$  and  $H_2O$  are, however, strongly sorbed. The corresponding isothermals rise at first slower than those of the other chabasites, indicating a smaller initial sorption energy, but attain ultimately even somewhat

chabasites.  $C_3H_8$  is only very weakly sorbed both by the sodium and by the potassium chabasite.

higher values. The water content is, however, the same, indicating that the saturation values (and thus the sorption space), may be unchanged in this chabasite too.

(d) *Potassium chabasite* sorbs as little nitrogen as the sodium product, and practically no hydrogen at all (at  $-190^\circ C$ ).  $H_2O$ , and  $CO_2$  are still strongly sorbed, although also to a somewhat smaller degree than by all other

### Discussion.

In general, the above results are in agreement with our assumption. The replacement of divalent by monovalent ions actually decreases the sorptive capacity of the crystals. The influence of the larger  $K^+$  is more pronounced than that of the smaller  $Na^+$  ions.

It is, however, difficult to interpret satisfactorily the details of the experimental results. The unchanged capacity for sorbing water and carbon dioxide indicates that space for sorption is not, or not essentially, decreased by the introduction of alkaline ions. The slightly smaller  $H_2O$  and  $CO_2$  content of K-chabasite may be due to the space occupied by the  $K^+$ -ions becoming unavailable for sorption. (The number of additional monovalent ions—about 0.8 mols. according to Table II.—is nearly equivalent to the decrease in the number of water molecules). This effect is, however, absent in the Na chabasite; and in the case of

FIG. 6.—Sorption by sodium-chabasite at  $-190^\circ C$ .

$K^+$  it may also be due to an incomplete saturation, i.e. to a smaller sorption energy. In any case, the small difference in the space available for sorption cannot account for the strong differences observed in sorption experiments with  $H_2$  and  $N_2$ . They must be due to *energetical* conditions. The results obtained with the *potassium chabasite* are consistent with an

assumption that the sorption energy both for hydrogen and nitrogen is decreased in the relation of about 5 : 1 (as compared with calcium chabasite). The sorption energies for carbon dioxide and water are also decreased, but to a much smaller degree.

The most difficult to understand are the results with *sodium chabasite*, in which the initial sorption energy for hydrogen appears to be reduced only by a factor 0.7, whereas the sorption energy for  $N_2$  is diminished roughly in a relation 3 : 1. Sodium chabasite can be described either as possessing an abnormally high sorptive capacity for hydrogen, or an especially low sorptive capacity for nitrogen (Fig. 6).

We may recall that the natural chabasite from Richmond (Victoria) which led to this investigation, had a sorptive capacity uniformly reduced (in the relation 3 : 1) for all the three gases  $H_2$ ,  $N_2$  and  $CO_2$ . This result illustrates the variety of the sorption effects occurring in alkali substituted chabasites.

### Sorption Formulæ.

The experimental results described above are not sufficiently complete to be used for quantitative representation by sorption formulæ as was done with the sorption isothermals of the natural chabasite in Paper I. We can here, however, improve the theoretical treatment given in that paper. Two possible states of the molecules sorbed by chabasite were mentioned there: (a) that of a "gaseous" sorbate, with molecules freely moving about in the cavities of the crystal, and (b) that of a "solid" sorbate, with molecules fixed to definite crystallographical positions. The first picture does not exclude the existence of periodical variations in the potential, or of more or less high "potential barriers" in certain lattice positions, thus accounting for the slowness of diffusion of the sorbate. The second picture must account for the existence of diffusion by assuming accidental interchanges of molecules between adjoining sorption centres. In this way, the two extreme hypotheses converge towards an intermediary picture of a "partially fixed" sorbate, which is probably nearest to the truth.

The actual state of a given sorbate, however, may be nearer to the one of the two pictures. It is therefore useful to have sorption formulæ for both limiting cases.

**(a) Gaseous Sorbate.**—The formulæ for the distribution of molecules between a gas phase and a zeolite was given in Paper I. as follows:

$$\frac{N_a}{N_g} = \frac{(V_a - bN_a)}{V_g} e^{\phi/RT} \quad (1)$$

$N_a$  is the number of molecules of the sorbate in the solid phase,  $N_g$  that in the gas phase,  $V_a$  the "sorption volume" of the crystal,  $b$  the volume required by a single molecule,  $V_g$  the volume of the gas phase,  $\phi$  the sorption energy (per mol.). Supposing  $b$  to be independent of the degree of saturation, we may assume  $V_a = bN_{\max.}$ , where  $N_{\max.}$  is the maximum number of molecules which can find place in the crystal. Hence

$$\frac{N_a}{N_g} = \frac{(N_{\max.} - N_a)b}{V_g} e^{\phi/RT} \quad (1')$$

For constant concentration of the sorbate  $\left(\frac{N_a}{N_{\max.} - N_a} = \text{const.}\right)$  the following vapour pressure formula (3) is derived from (1)

$$\log_e p_{\text{atm.}} = -\frac{\phi}{RT} + \log_e T + \log \frac{N_g}{N_{\max.} - N_a} - \log_e N_A T_0 b \quad (2)$$

where  $N_A$  is the number of molecules in c.c. of the gas at  $t = 0^\circ \text{C.}$  and  $p = 1 \text{ atm.}^4$

**(b) Solid Sorbate.**—The statement in Paper I. that "formula (1) holds also for the case of a fixed number of sorbing centres,  $b$  meaning in this case the volume of each centre and  $V_a$  that of all of them together" requires correction. The distribution of molecules between

<sup>4</sup> M. H. Hey, (*Mineralogical Magazine*, 1935, 24, 99) derived, by kinetic considerations, a vapour pressure formula very similar to (2) (but with slightly different meaning of some constants). Some constants in his formulæ are, however, related to the special mechanism of evaporation and condensation which he uses for derivation—a result not in accordance with thermodynamics, which requires that a formula describing an equilibrium shall contain nothing about the mechanism by which this equilibrium is reached.

gas phase and a fixed number of sorption centres depends on the *number* of unoccupied centres only, and the notion of the "volume of a sorption centre" is an unnecessary complication. Moreover, law (1) does not apply unchanged to a distribution of this kind. In passing from the gaseous state into that of a *solid* sorbate, the molecules lose not only their potential energy of sorption  $\phi$  but also their kinetic energy. The distribution law is therefore more complicated. The probability of finding a molecule in the gas phase (volume  $V_g$ , temperature  $T$ ) is, according to quantum statistics :

$$P_{\text{gas}} = \int_{E=0}^{\infty} V_g \frac{4\sqrt{2\pi m^3} E^{\frac{1}{2}}}{h^3} e^{-E/kT} dE.$$

The probability of finding the molecule in the solid sorbate is :

$$P_{\text{solid}} = (N_{\text{max.}} - N_a) e^{\phi/RT}$$

and the distribution law is therefore

$$\frac{N_a}{N_g} = \frac{N_{\text{max.}} - N_a}{V_g} \frac{h^3 N_A^3}{(2\pi MRT)^{\frac{3}{2}}} e^{\phi/RT} \quad (3)$$

a formula which differs essentially from (1) by the occurrence of the factor  $T^{\frac{3}{2}}$ , and by the molecular weight  $M$  replacing the molecular volume  $b$  in the rôle of a characteristic constant of the sorbate.

The vapour pressure formula derived from (3) is :

$$\log_e p_{\text{atm.}} = -\frac{\phi}{RT} + \frac{5}{2} \log_e T + \log_e \frac{N_a}{N_{\text{max.}} - N_a} + \log_e \frac{(2\pi RM)^{\frac{3}{2}}}{h^3 N_A^4} \quad (4)$$

Equation (4) differs from the ordinary quantum theoretical vapour pressure formula of a homogeneous ideal solid body by the occurrence of the characteristic "saturation term"

$$\log \frac{N_a}{N_{\text{max.}} - N_a}$$

**(c) Vibrating Sorbate Molecules.**—Since the sorption energies are not greater than 30,000 Cals. per mol., the quanta corresponding to the vibrations of the molecules around their equilibrium positions must be of the order of 1000 Cals. (300 cm.<sup>-1</sup>) or smaller and these vibrations are by no means "frozen" at temperatures above 100°<sub>abs.</sub> (which were used in most sorption experiments). The law of distribution of molecules between gas and sorbate is in this case :

$$\frac{N_a}{N_g} = \frac{(N_{\text{max.}} - N_a)}{V_g} \sum_v e^{-E_v/RT} \frac{h^3 N_A^3}{(2\pi MRT)^{\frac{3}{2}}} e^{\phi/RT} \quad (5)$$

and the corresponding vapour pressure formula :

$$\begin{aligned} \log_e p_{\text{atm.}} = & -\frac{\phi}{RT} + \frac{5}{2} \log_e T + \log_e \frac{N_a}{N_{\text{max.}} - N_a} \\ & - \log_e \sum_v e^{-E_v/RT} + \log_e \frac{(2\pi RM)^{\frac{3}{2}}}{h^3 N_A^4} \quad (6) \end{aligned}$$

In these formulæ,  $E_v$  is the vibrational energy (per mol.) corresponding to the state with the vibrational quantum number  $v$ .

(d) **Isothermals.**—From all the three formulæ (2), (4) and (6), we obtain the following isothermal equations:

$$\frac{N_a}{N_{\max} - N_a} = ap; \quad N_a = \frac{apN_{\max}}{1 + ap} (a = \text{const}) . \quad (7)$$

A law of this form must hold for the sorption isothermals independently of the "gaseous," "solid" or "semi-solid" state of the sorbate, provided only that  $\phi$  is a constant independent of the saturation  $N_a/N_{\max}$ .

The experimental sorption isothermals of chabasite, however, never fulfil law (7). This shows clearly that the sorption energy is dependent on saturation. Two possibilities may be considered: the sorption energy may either decrease continuously with increasing sorption, or it may change in steps. In Paper I. we made the mistake of expecting that sudden changes of the sorption energy must reveal themselves by discontinuities or inflexions in the sorption isothermals. This is not true. If, for instance, the crystal contains two kinds of sorption centers,  $N_1$  (with the energy  $\phi_1$ ), and  $N_2$  (with the energy  $\phi_2$ ), then the distribution between gas phase and each set of centers will be independent of the existence of the second set and given by a formula of the kind (7). The total number of molecules in the sorbed state will be:

$$(N_a)_1 + (N_a)_2 = p \left( \frac{a_1(N_{\max})_1}{1 + a_1p} + \frac{a_2(N_{\max})_2}{1 + a_2p} \right) . \quad (8)$$

This equation represents a smooth function without any discontinuities or inflexions. Obviously, a continuous change of  $\phi$  with  $N_a/N_{\max}$  may be expected to occur in the case of a "gaseous" or nearly gaseous sorbate, whereas the existence of a discrete set of values  $\phi_1, \phi_2, \dots$  is more characteristic of a "solid" sorbate with a number of different crystallographic positions occupied by the molecules of the sorbate.

(e) **Saturation.**—In the case of a fixed number of sorption centers, the number of molecules corresponding to the saturation state must be the same for all kinds of sorbates, or, alternatively, only a few widely separated saturation values may be found, forming a small whole number series. This may occur either in the case of larger molecules occupying two or more centres, or in the case of a particular set of centers being unavailable for some kind of sorbate. In the case of a gaseous sorbate, the saturation values may vary continuously according to the size and shape of the molecules.

In Paper I. we used formula (1) for the representation of the isothermals, considered  $\phi$  as a continuous function of the concentration and extrapolated individual saturation values for all gases investigated. In doing so, we practically adopted the hypothesis of the "gaseous" sorbate.

After the appearance of that paper, it has been, however, suggested<sup>5</sup> that chabasite possesses two crystallographical positions which are vacant in the dehydrated lattice. Under these circumstances, two different saturation values and two different sorption energies for each gas may be expected. Hey suggested that the saturation values extrapolated in our previous paper may be arranged in two groups—some being close to 330 c.c./gm. (corresponding to 12 molecules of sorbate per unit cell) and the others to about  $\frac{1}{3}$  of this value. Fig. 8 in Paper I. shows that this interpretation is not incompatible with the experiments

<sup>5</sup> See A. Tiselius, *Z. physik. Chemie*, 1935, **A**, **174**, 401.

made with natural calcium chabasite. The results obtained with the substituted chabasites and illustrated by Figs. 2-5 in this paper are, however, more difficult to reconcile with this scheme. To interpret them would require much more than two different kinds of centers. Besides the saturation values 330 and 165 c.c., those lying in the neighbourhood of 80 c.c. and 20 c.c. are suggested by the slope of some curves.

By assuming 4 or more different kinds of positions, each having its own characteristic sorption energy, one has in hand enough independent constants to be able to represent all the experimental isothermals. A representation of this kind is, however, of no great value in the actual state of the experimental material available. Fuller investigations of the sorption equilibrium may, however, give, with the help of the above derived formulæ, information about the state of the sorbates under different conditions.

The experimental part of this paper forms one part of the dissertation presented by Mr. W. C. Wood to the Faculty of Science of the University of Göttingen. Results of an investigation of the electrical properties of zeolites, which were included in this dissertation, were communicated on a previous occasion.<sup>5</sup>

The experiments were carried out in the Minerological Institute of the University of Göttingen, to whose Director, Professor V. M. Goldschmidt (now is Oslo), we are highly indebted for his kind interest in this work and many valuable suggestions. We also thank Dr. E. Thilo for valuable advice in the analytical part of this work.

## THE ABSORPTION SPECTRUM OF AQUEOUS CHLORINE AND HYDROGEN PEROXIDE VAPOUR.

BY W. C. FERGUSON, L. SLOTIN AND D. W. G. STYLE.

*Received 2nd April, 1936.*

The extinction coefficients for gaseous chlorine have been accurately determined by v. Halban and Siedentopf<sup>1</sup> for the chief mercury arc lines, and Barratt and Stein<sup>2</sup> and Gillam and Morton<sup>3</sup> have made measurements of the absorption of solutions of the gas in carbon tetrachloride, which show that the absorption spectrum in this solvent is approximately the same as that in the gaseous state.

The absorption of aqueous solutions have an especial interest on account of the thermal hydrolysis and photochemical reactivity of such solutions. According to E. S. Ssokolowa and P. I. Ssokolow<sup>4</sup> the extinction coefficients of aqueous chlorine are, for the wave-length 436, 454, and 463 mμ, approximately the same as those of the gas. This is in agreement with the earlier measurements of Allmand, Cunliffe and Maddison,<sup>5</sup> who concluded that within the limits of their, admittedly,

<sup>1</sup> *Z. physik. Chem.*, 1922, **103**, 513.

<sup>2</sup> *Proc. Roy. Soc., A*, 1929, **122**, 582.

<sup>3</sup> *J. Russ. Physic. Chem.*, 1930, **62**, 319.

<sup>4</sup> *J. Chem. Soc.*, 1927, 655.

<sup>5</sup> *Ibid.*, **124**, 604.

rather large experimental error there was no marked difference between the extinction coefficients of gaseous chlorine and its aqueous solution for the wave-lengths 436, 405, and 365  $m\mu$ .

In the present work these measurements are repeated and extended so as to cover the whole spectrum between 420 and 220  $m\mu$ . As, however, the thermal hydrolysis results in the production of hypochlorous and hydrochloric acids it was necessary to determine the magnitude of the corrections due to these substances. The degree of hydrolysis and consequently the concentrations of the acids present could be readily calculated from the values of the equilibrium constant given in Lewis and Randall's *Thermodynamics*, page 508. Owing to the very slight absorption of the chloride ion,<sup>6</sup> no correction is necessary for the absorption of the hydrochloric acid. Hypochlorous acid on

the other hand absorbs considerably throughout the spectral region investigated.

As the existing measurements on hypochlorous acid were neither extensive nor accurate enough, it was necessary as a preliminary to determine its absorption spectrum.

**Hypochlorous Acid.**—The acid was prepared by distillation of a mixture of bleaching powder, boric acid and water under reduced pressure, the distillate being redistilled from silver sulphate in order to remove traces of chloride. The approximately 0.2 *M.* solutions so prepared were diluted as required.

For the absorption measurements a Judd-Lewis sector photometer in conjunction with a Hilger E.2 quartz spectrograph and an iron spark

<sup>6</sup> Frommers and Menschik ; *Z. physik. Chem.*, 1930, 137, 439.

was used. The points of equal density in the photographs were determined visually. The absorption cells were made up of drilled glass blocks over the ground plane-paralleled ends of which crystal quartz plates were clamped. Although no cement was used, leakage was insignificant. Various depths of solution between 5.0 and 0.1 cm. were used. The reflection and other light losses were balanced by cells of similar depth filled with water. Transmissions greater than 50 per cent. were not used in order to avoid errors due to small differences in the characteristics of the cells. The concentrations were determined iodimetrically.

The mean results of these measurements are shown in Fig. 1 in which logarithms of the decadic extinction coefficients are plotted against the wave-length. No dependence of the extinction coefficient upon the concentration could be detected within the concentration range of 0.017 — 0.15 *M*.

**Chlorine Water.**—For the preparation of the chlorine water both commercial chlorine taken direct from a cylinder of the liquefied gas and

FIG. 2.

chlorine purified by washing with water, liquefaction and distillation were used. The purified chlorine gave somewhat lower values of the extinction coefficient particularly at shorter wave-lengths where the correction for the hypochlorous acid formed by the hydrolysis is of most importance.

In order to avoid concentration changes, the chlorine solutions were prepared by passing the chlorine through water contained in a special all-glass storage vessel. From this vessel the solution could be siphoned out either into the absorption cell or into a special pipette designed by Mr. H. N. Ridyard and K. W. Young for accurate measurements on chlorine solutions. The air replacing the chlorine water removed, passed through two bubblers containing solution of the same strength as that in the main vessel.

The concentrations of the chlorine-water was determined both immediately before and immediately after filling the absorption cell, the mean value being taken as that of the solution in the cell.

The extinction coefficients of the unhydrolysed chlorine were calculated from the expression

$$\log_{10} \frac{I_0}{I} = d(\alpha_{Cl_2}[Cl_2] + \alpha_{HOCl}[HOCl])$$

in which  $\alpha_{Cl_2}$  and  $\alpha_{HOCl}$  are the extinction coefficients of  $Cl_2$  and  $HOCl$  respectively,  $I_0$  and  $I$  respectively the incident and transmitted light intensities, and  $d$  the thickness of the absorbing layer of solution.

As the degree of hydrolysis, and consequently the correction for the absorption of hydrochlorous acid increases with the dilution, concentrations of less than 0.04 *M.* could not be used for quantitative measurements. The results obtained with the purified chlorine are plotted in Fig. 2.

Since the absorption spectrums of aqueous hypochlorous acid might differ considerably from that of the vapour, and in particular since discontinuous absorption if it occurs could only be detected in the vapour phase, the absorption of the vapour was investigated. At the same time the absorption of hydrogen peroxide vapour was also redetermined as it seemed probable that the work of Urey, Dawsey and Rice<sup>7</sup> was in error, since their results for aqueous solutions differ considerably from the concordant results of several other workers.<sup>8</sup> No indication of any discontinuity in the absorption of hypochlorous acid vapour could be detected between 230 and 390  $m\mu$ , using a Hilger E. 2 Spectrograph.

**Hydrogen Peroxide and Hypochlorous Acid Vapours.**—Since neither of these substances can be obtained at a high concentration in the vapour phase, it is necessary to employ a

long absorption tube if the absorption measurements are to be reliable. A translucent silica tube 10 metres in length and 2.5 cm. in diameter with fused on transparent end plates, heated electrically to about 45° C. was used. The hypochlorous acid vapour was obtained from aqueous solutions prepared by the method already described and the peroxide vapour from redistilled Merck's "Perhydrol."

FIG. 3.

To one end of the absorption tube B (Fig. 3) was sealed a quartz flask A, containing a solution of the vapour to be investigated. During absorption measurements the vapour was distilled through B into the liquid air trap E, a convenient pressure being maintained in B by the capillary D and control of the tap H. A "Hyvac" pump continually removed permanent gas. In order to measure the pressure in B a narrow bore lead was taken from one end of B to the manometer G. Peroxide vapour was prevented from reaching the manometric liquid by manganese dioxide heated to 100° C. contained in the bulb C, while the water vapour initially present or formed by the decomposition of the peroxide was frozen out in the trap F, so that only oxygen reached the manometer. With

<sup>7</sup> Urey, Dawsey and Rice: *J.A.C.S.*, 1929, **51**, 1371.

<sup>8</sup> Henri and Wurmser; *C.R.*, 1913, **156**, 1012; Rieche and Lederle, *Ber.*, 1929, **62**, 2573; Allmand and Style, *J. Chem. Soc.*, 1930, 596.

hypochlorous acid, C was replaced by a capillary leak open to the atmosphere in order to supply the gas to operate the manometer.

After each exposure the condensate in the trap E was melted and the molal fraction of peroxide or hypochlorous acid determined by the usual analytical methods. The temperature and total pressure in the absorption tube being known, the concentrations of the absorbing vapours could be readily calculated. These lay between 1 and  $4 \times 10^{-5}$  gm. mols./litre with hypochlorous acid and between  $5 \times 10^{-5}$  and  $5 \times 10^{-6}$  with hydrogen peroxide.

A hydrogen discharge between stainless steel electrodes in a water-cooled silica tube served as the light source. Before entering the absorption tube the light was rendered approximately parallel by the sector box lens system of a dismantled Judd-Lewis sector photometer. The absorption of the peroxide vapour was determined by taking pairs of photographs with the same time of exposure without moving the photo-

graphic plate but with different adjacent portions of the slit of the spectrograph exposed, one with the tube evacuated (the tap H being closed) and the other with peroxide vapour flowing through the tube and the sector adjusted to give the maximum transmission. The match points were determined visually. The accuracy of this method was checked by determining the extinction coefficients of chlorine, values within 5 per cent.

FIG. 4.

of those given by v. Halban and Siedentopf being obtained.

The instability of hypochlorous acid and the weak absorption usually obtained with it necessitated the adoption of a different procedure with this substance.

A calibration series of spectra was photographed through the evacuated tube with constant time of exposure, but with the sector adjusted to give different transmissions. Photographs were then taken with the same exposure but with hypochlorous acid vapour flowing through the tube and the sector set to give the maximum transmission. The absorption of the vapour at a number of wave-lengths was then found by comparing the densities of the photographs taken through the vapour with the calibration series by means of a recording micro-photometer.

The results for hydrogen peroxide are shown in Fig. 4 and the results from a few representative plates obtained with hypochlorous acid in Fig. 1.

### Discussion.

Although, as can be seen from the scattering of the extinction coefficients of gaseous hypochlorous acid, no great accuracy can be claimed, there can be no doubt that there is a very considerable difference between the absorption of this substance in the vapour and dissolved states. This difference cannot be ascribed to either chlorine monoxide or chlorine dioxide, since the absorption in no way resembles that of the monoxide,<sup>9</sup> and the very easily detectable bands of the dioxide were entirely absent from all plates used for measurement. The dioxide bands did, however, sometimes appear if the hypochlorous acid solution was not freshly prepared. The very marked depression of the transition probability on passing from the vapour to the dissolved state is rather exceptional since chlorine is scarcely affected at the longer wave-lengths, and with hydrogen peroxide the effect of dissolution seems to be to simultaneously increase the maximum absorption and make the band narrower. The mean time of contact of the vapour with the heated tube was only of the order of 5 seconds, but no attempt was made to keep it constant from exposure to exposure, so that the difference between solution and vapour can scarcely be accounted for by assuming that some 90 per cent. of the vapour decomposed during its passage through the absorption tube. The concentration of the condensate was moreover too great to allow of the assumption that any extensive decomposition had occurred. The large effect of the solvent may perhaps be due to the asymmetry of the hypochlorous acid molecule, and its consequent considerable interaction with the water dipoles.

The dissociation products which might be obtained from the hypochlorous acid molecule are:  $\text{OH} + \text{Cl}$  (either or both being excited), requiring 55 Cals. for unexcited products,  $\text{HCl} + \text{O}({}^3P)$ , requiring 57 Cals.,  $\text{HCl} + \text{O}({}^1D)$  requiring 102 Cals. and  $\text{H} + \text{ClO}$  requiring 109 Cals., if the heat solution of hypochlorous acid is taken as 10 Cals. and the heat of dissociation of  $\text{ClO}$  is 50 Cals.<sup>10</sup> Either of the two first of these might be produced by light absorption in the longer wave-length band. The failure to detect the presence of any discontinuity in the absorption even at the wave-length where the extinction coefficient is a minimum ( $\lambda \sim 277 \text{ m}\mu$ ) excludes any process requiring more than 102 Cals. from responsibility for the absorption at shorter wave-lengths. Dissociation into  $\text{H} + \text{ClO}$  can thus be left out of account unless this band is not simple, as it appears to be.  $\text{HCl} + \text{O}({}^1D)$  remain, however, just possible.

The maximum of the second band lies outside the region covered by these measurements, but from the general trend of the curve might be expected to occur at about  $210 \text{ m}\mu$ , giving about 47 Cals. as the energy separation of the two maxima. This approximates to the difference between the two oxygen terms  ${}^1D - {}^3P = 45$  Cals. Notwithstanding this apparent agreement the available evidence scarcely justifies the assignment of any one of the three possible dissociation processes to either band.

The effect of water upon the absorption of chlorine is zero within the experimental error for wave-lengths between  $350$  and  $420 \text{ m}\mu$ .

<sup>9</sup> Goodeve and Wallace, *Trans. Faraday Soc.*, 1930, **26**, 254. Also ref. 10.

<sup>10</sup> Finkelburg, Schumacher and Stieger, *Z. physik. Chem.*, B, 1931, **15**, 127.

At shorter wave-lengths, however, there is an increase in the absorption culminating in the appearance of a new band below  $270\text{ m}\mu$ , the maximum of which is not attained within the limits of our measurements.

A similar but more intense change in the absorption has been found on dissolution in strong aqueous hydrochloric acid (4 to 10 molar), when a very intense absorption sets in below  $290\text{ m}\mu$ , the absorption at longer wave-lengths remaining meanwhile similar to that of the gas. If the hydrochloric acid contained hydrobromic acid the long wave-length maximum shifted to  $380\text{ m}\mu$ , the position of the maximum of bromine chloride in carbon tetrachloride.<sup>11</sup> According to the data of Forbes and Fuoss<sup>12</sup> the chlorine would have reacted almost completely to form bromine chloride under our conditions. The absorption obtained with the solutions containing hydrobromic acid was very similar to that of  $\text{BrCl}_2^-$  excepting that the absorption at shorter wave-lengths found by us was much stronger than that reported by Gilbert, Goldstein and Lowry.<sup>13</sup> This difference is readily accounted for if the complex ion is considerably dissociated if a large excess of chloride ion is not present.

By analogy the ion  $\text{Cl}_2^-$  is presumably responsible for the absorption obtained with chlorine in hydrochloric acid solution, and further, the difference between the absorption of gaseous chlorine and its aqueous solution (which is indicated by the dotted curve of Fig. 2) may be ascribed to the ion  $\text{Cl}_2\text{OH}^-$  or perhaps the molecule  $\text{HCl}_2\text{OH}$ . Though possibly merely a coincidence it is worth noting that this difference rather closely resembles the absorption of hypochlorous acid vapour (Fig. 1).

In view of the experimental methods employed, it would seem that the present values of the extinction coefficients of hydrogen peroxide are to be preferred to those of Urey, Dawsey and Rice.

### Summary.

The absorption spectra of aqueous chlorine and hypochlorous acid solutions and of the vapours of hypochlorous acid and hydrogen peroxide have been investigated.

The interpretation of the observations is discussed.

# THE PROTON AFFINITIES OF SPARINGLY SOLUBLE BASES: BENZIDINE.

BY E. B. R. PRIDEAUX AND J. H. PARKINSON.

*Received 23rd April, 1936.*

The dissociation constants of bases having solubilities below about 0.001 mols./litre cannot be determined by the ordinary methods with the same accuracy as those of soluble bases, on account of the low concentrations and consequent lack of hydrogen ion regulating power, *e.g.*, of the equimolecular free base, salt mixtures. The first constant of benzidine was, however, determined by Pring<sup>1</sup> who measured  $[H^+]$  of the 0.001 *N.* hydrochloride and base (*a*) by the quinhydrone (*b*) by the hydrogen, electrode and (*c*) colorimetrically, and found (classical) basic dissociation constants  $k_B = 1.7 \times 10^{-9}$ ,  $1.45 \times 10^{-9}$  and  $1.58 \times 10^{-9}$  respectively. If we take the mean value of  $1.58 \times 10^{-9}$  and express the basic constant as a hydrolysis constant  $k_W/k_B$ , which is also an apparent acidic constant  $k_H$ , then  $pk_H$  or  $pk_1 = 5.2$ .

Since  $1/k$  represents the proton affinity of the base which is given by  $[BH^+]/[B][H^+]$ , the magnitude of  $pk_1$  is a measure of the affinity of the base for the first proton.

In order to obtain a mean value of this constant (which is often found to vary slightly with the degree of neutralisation, a number of points on each side of the half-equivalence point have been obtained, and corrected by the equation :

$$pk_1 = p_H + \log \frac{[BH^+] - [H^+]}{[B] + [H^+]}$$

10 c.c. of an *M*/2000 solution of the base containing 0.092 g./litre were treated with 0.01176 *N* HCl, 0.135 to 0.335 c.c., added from a micro-burette, and the  $p_H$  values determined by matching with B.D.H. universal indicator in a test-tube comparator. Mean  $pk_1 = 4.97$ .

The hydrolysis of *M*/2000 BHCl was investigated with B.D.H. universal, bromocresol blue and bromophenol blue, indicators. The mean  $p_H$  was 4.3. Applying the usual equation :

$$p_H = 7 - \frac{1}{2}pk_B - \frac{1}{2} \log C \quad . \quad . \quad . \quad (2)$$

we find,  $pk_B = 8.9$ ,  $pk_1 = 5.1$ .

Although this method apparently gives a correct result, yet it must be noted that the simple hydrolysis equation is not really applicable, since the second constant has an exponent which only differs from that of the first by little more than a unit. The  $p_H$  of the first equivalence point is intermediate between  $pk_1$  and  $pk_2$ , so that the general equation of a diacid base should be used, which may be expressed in the form :

$$[H^+]^2 = \frac{k_1 k_2 C}{k_1 - C}$$

in which  $k_1$ ,  $k_2$  are the apparent acidic constants. Taking negative exponents of  $[H^+]$ ,  $k_1$  and  $k_2$ , we obtain :

$$p_H = \frac{1}{2}(pk_1 + pk_2) \quad . \quad . \quad . \quad (3)$$

<sup>1</sup> *Trans. Faraday Soc.*, 1924, 19, 705.

Inserting the value of  $pk_1 = 5.0$ , then  $pk_2 = 3.4$ , which is 0.4 units less than that found experimentally.

The second constant was determined by adding 0.0294 *N* NaOH from a microburette to 10 c.c. of the 0.005 *M* base dihydrochloride in the presence of dimethylaminoazobenzene and methyl orange. The equation contains a hydrolysis correction which is rather high :

$$pk_2 = p_H + \log \frac{[BH_2^{**}] - [H^*]}{[BH^*] + [H^*]} \quad (4)$$

in which  $[BH]$  is the uncorrected amount of monohydrochloride corresponding to the addition of  $x$  c.c. of alkali. The calculated  $pk_2$  varied between 3.6 and 3.9, the mean of 10 results being 3.75.

As already remarked, this exponent is too high to yield the experimental equivalence point of monacid base. While, however, the first constant was determined in solutions so dilute that no correction is needed for total "ionic strength," the second was determined in more concentrated solutions, and should be corrected by some function of  $C$ , which would probably give a lower value to the ideal or limiting  $pk_2$ .

### Dissociation Constants in Aqueous-Alcoholic Solutions.

The constants in methyl alcohol, 50 per cent., were found by Kuhn and Zumstein,<sup>2</sup> who measured the E.M.F. of the combination:  $H_2PtB$ ,  $BHCl$  3.5 *N*  $KCl$ , 3.5 *N*  $KCl$ ,  $HgCl$   $Hg$  at 20°. The normal potential of the calomel 3.5 *N* potassium chloride was taken as 250 mv. The results are expressed by the general equations corrected for activities of  $BH$  and  $BH_2$  at the ionic concentrations.

$$pk_1 = pa_H - \log [B]/[BH^*] - 0.43\sqrt{C}$$

$$pk_2 = pa_H - \log \frac{[BH^*] + [H^*]}{[BH_2^{**}] - [H^*]} - 1.28\sqrt{C}.$$

In these solutions,  $pk_1 = 4.89$ ,  $pk_2 = 3.74$ .

The  $pk$  values of several bases in mixtures of ethyl alcohol and water have been obtained electrometrically, and the results extrapolated to zero concentration of alcohol.<sup>3</sup>

**Experimental.**—Pure benzidine (0.3683 g.) was dissolved in 100 c.c. of dry alcohol. 5 c.c. portions of this solution were made to 50 c.c. by adding appropriate amounts of standard hydrochloric acid, water and alcohol, in order to give a series of solutions containing 10 up to 70 per cent. of alcohol and 0.04 molar half-neutralised base. The E.M.F. at 20° of the chain :

$H_2Pt$  alcoholic base —  $HCl$  saturated  $KCl$ , agar sat.  $KCl$

$HgCl$   $Hg$  gave  $p_H = \frac{E - E_0}{0.058}$ , in which  $E_0 = 246.4$  mv.

The results are shown graphically in Figs.

For the *monacid* base  $pk_1$  is 4.60 in 70 per cent. and 4.99 in 15 per cent. alcohol, extrapolated value, 5.09.

For the *diacid* base,  $pk_2$  is 3.42 in 60 per cent. alcohol and 3.67 in 10 per cent., extrapolated value, 3.79.

### Systems Containing Solid Base, Relation between Dissociation and Solubility:

Heterogeneous systems would seem to be particularly suitable for determining constants of very slightly soluble bases, since the solutions are well buffered as well as dilute. It is first necessary to develop the appropriate equations.

**Solid Base present.**—As before, the free uncharged base will be represented by  $B$ , the univalent kation by  $BH^+$  and the divalent by  $BH^{++}$ . The concentrations of the various ions are regulated by the dissociation constant,  $k_B$ , the solubility product of the base:

$$[BH^+][OH^-] = k_B B = L_B \quad (5)$$

and, if solid salt is also present, by its solubility product:

$$[BH^+][Cl^-] = L_S \quad (6)$$

From electrical neutrality:

$$[BH^+] = [Cl^-] + \frac{k_W}{[H^+]} - [H^+] \quad (7)$$

The solutions are all acid, so that:

$$[BH^+] = [Cl^-] - [H^+] \quad (8)$$

$[Cl^-]$  can be calculated or obtained by titration, hence  $L_B$  from equation (5). In order to determine  $k_B = \frac{[BH^+]K_W}{[B][H^+]}$ , it is necessary to determine also  $B$  the concentration of undissociated base, which is practically equal to the solubility in pure water.

**Solid Base and Solid Salt present.**—In equation (7) substitute values of  $[Cl^-]$  from (6),  $[OH^-]$  from (5) and  $[H^+] = \frac{[BH^+] \times K_W}{L_B}$  and obtain:

$$[BH^+] = \left\{ \frac{L_B(L_S + L_B)}{L_B + k_W} \right\}^{\frac{1}{2}} \quad (9)$$

The results showed that  $L_B$  can be neglected in comparison with  $L_S$  and therefore:

$$[BH^+] = \left\{ \frac{L_B L_S}{L_B + k_W} \right\}^{\frac{1}{2}} \quad (10)$$

These express the conclusion that the saturated solutions maintain constant concentrations of the hydrogen and other ions.

**Experimental.**—Solubility was determined by saturating a large volume of water with the base at 30° C. then cooling to and maintaining at 25°. 250 c.c. were extracted successively with 15 c.c. of chloroform. A blank experiment had shown that extraction was complete; the residual aqueous part gave no blue colour with a few drops of potassium dichromate solution, and therefore contained less than 1 in 50,000 of base. Evaporation of the united extracts showed a solubility of 0.0916 g./litre.

Saturated benzidine solutions in portions of 25 c.c. were treated with 0.2 g. of the solid base, and then with 1.3 to 3.5 c.c. of 0.09173 N HCl. A constant  $p_H$  of 4.3 was registered with bromocresol green in a Lovibond disc comparator.

100 c.c. portions of a saturated solution containing solid base were treated with varying amounts of 0.1 N HCl, shaken vigorously and allowed

to stand for a week, when the constancy of  $p_H = 4.3$  was verified. The chloride ion was determined by thiocyanate titration, and was  $6.37$  to  $6.42 \times 10^{-3}$  g. ions per litre as  $8$  to  $15$  c.c. of the hydrochloric acid were added to  $30$  c.c. of the base solution.

From the values of  $[BH^+]$ ,  $[H^+]$  and  $[B]$  obtained as above, the value of  $pk_B$  was found and is expressed as  $pk_1 = 5.23$ .

Solubility product of base,

$$L_B = k_B B = 1.72 \times 10^{-9} \times 7.24 \times 10^{-4} = 1.25 \times 10^{-12}.$$

Solubility product of monohydrochloride,

$$[BH^+][Cl^-] = 6.37 \times 10^{-3} \times 6.4 \times 10^{-4} = 4.08 \times 10^{-6}.$$

#### Summary of Affinity Constants ( $k_w = 1.10 \times 10^{-14}$ ).

Method and Workers.	$k_B \times 10^9$ .	$pk_1$ .	$pk_2$ .

## THE INFLUENCE OF ULTRASONIC WAVES ON GELS.

BY H. FREUNDLICH AND K. SÖLLNER.

Received 23rd April, 1936.

This paper deals with the mechanism of the influence of ultrasonic waves on thixotropic gels and with their peptising effect in general.

### 1. The Liquefaction of Thixotropic Gels.

Some years ago<sup>1</sup> it was reported that thixotropic hydrogels (e.g. those of iron and aluminium oxides, bentonite, barium malonate) and several organo-gels are readily rendered fluid when irradiated with ultrasonic waves of high intensity for several seconds, the time of spontaneous solidification being the same as after vehement shaking. It was proved that this liquefaction is not due to thermal effects (which, after so short an irradiation, are small), as these gels have no tendency to soften or melt when moderately heated; indeed iron and aluminium oxides spontaneously solidify more rapidly at higher temperatures.<sup>2</sup>

<sup>1</sup> H. Freundlich, *Kapillarchemie* 4, *Ausgabe*, II. Bd. 1932, p. 616; H. Freundlich, F. Rogowski and K. Söllner, *Z. physik. Chem., A*, 1932, 160, 469; *Kolloid-Beihfte*, 1933, 37, 223; N. Marinesco, *C.R.*, 1932, 194, 1824.

<sup>2</sup> A. Szegevari and E. Schalek, *Koll. Z.*, 1923, 33, 326; H. Freundlich, F. Rogowski, and K. Söllner, *Kolloid-Beihfte*,<sup>1</sup>

The liquefaction of gels contained in test tubes commences at the interface gel/air, the upper parts becoming liquid at once when irradiated with high energy. With iron oxide gels the process of liquefaction may easily be observed, as the colour of the gel turns to a much darker brown. The liquefied parts move rapidly and drops are thrown out forcibly from the surface. From the very start of the irradiation the whole gels shows brown spots, having a marbled appearance and on longer irradiation the amount of liquid increases, until the whole mass has become liquid.

The importance of the gel/air interfaces in the process of liquefaction may be strikingly demonstrated with transparent aluminium oxide gels,<sup>3</sup> on shaking which, air-bubbles may be distributed throughout the whole mass. The creaming-up of these bubbles stops when the sol reverts to a gel, but the latter then contains numerous air-bubbles. When irradiated (preferably with not too high an energy) the bubbles move upwards, coalescing more or less and stopping at once when the irradiation ceases.<sup>4</sup> Their movement is particularly strong where the oil fountain touches the test tube. In this way air-bubbles may be expelled from the gel, the latter not being rendered wholly fluid; this becomes evident on turning the test tube upside down. Only a thin layer of gel round the bubbles is liquefied, and through this the latter move upwards. Sometimes under these conditions the bubbles tend to form stationary wave patterns.<sup>5, 6</sup>

When a test tube containing a thixotropic gel is turned upside down and then dipped into the oil fountain the gel does not fall down as a lump, but is rendered liquid at the lower surface; the liquid then runs down the walls of the tube and liquefaction proceeds on the surface until the whole mass is liquid.

In a previous paper a mechanism of emulsification by ultrasonic waves was suggested<sup>7</sup> and it seemed worth while to investigate, how far the liquefaction of gels may be explained in the same manner.

It was shown that emulsification in oil/water systems is due to cavitation or more correctly to the vehement collapse of cavities. These cavities form when the liquid is unduly stretched during the expansion phases of the sound waves; if an external force (e.g. an external gas pressure) causes these cavities to collapse, violent mechanical processes such as emulsification occur.

This mechanism holds also for the liquefaction of gels; if liquefaction ceases when cavitation can no longer be effective, it must be attributed to cavitation.

Effective cavitation may be prevented,<sup>7</sup> either by experimenting *in vacuo* so that no external force acts upon the cavities to cause them to collapse, or by applying such a high external pressure that no cavities are formed. Under neither of these conditions do ultrasonics render thixotropic gels fluid.

#### Experiments *in vacuo*.

Two samples of thixotropic iron oxide sol, having the same time of solidification when liquefied by shaking, were sealed in test tubes, the one (a) under normal pressure and saturated with air, the other (b) *in*

<sup>3</sup> H. Freundlich, F. Rogowski and K. Söllner.<sup>1</sup>

<sup>4</sup> See Fig. 3 on page 236 *Kolloid-Beihfte*, 1933, 37.

<sup>5</sup> E. Newton Harvey, *Biol. Bull.*, 1930, 59, 306; K. Söllner and C. Bondy, *Trans. Faraday Soc.*, 1936, 32, 616.

<sup>6</sup> Solid particles also move in these gels on irradiation, but very much more slowly. If somewhat small they form stationary wave patterns under suitable conditions; if too big and too heavy, the radiation drives them to and fro, thus liquefying the gel around them slowly till they sink down in course of time.

<sup>7</sup> C. Bondy and K. Söllner, *Trans. Faraday Soc.*, 1935, 31, 835.

*vacuo* after careful degassing. When exposed to ultrasonic waves of moderate energy, tube (a) readily liquefied, starting mainly from the top; tube (b) hardly changed, a thin layer only, at the surface being somewhat disturbed after a long time.

With very high energies drops of the gel were torn off and thrown upwards; an occasional small brown (liquefied) spot appeared also in some samples *in vacuo*, as it is difficult to make the gel absolutely gas-free, but even after prolonged irradiation only the top layer of the gel is at all disturbed, its "viscosity" still being obviously very high; the gel as a whole being unaffected. The tearing away of drops from the surface is always observed in the oil fountain over the vibrating quartz plate.\* With the air-saturated gel, liquefaction was effected very rapidly.

When these experiments are performed in long tubes<sup>8</sup> the results are still more pronounced. Only a slight surface movement is observed *in vacuo*, but with the air-saturated gel liquefaction always occurs (where in the emulsification experiments emulsification was seen), preferably at the top and secondly where the oil fountain touches the glass, the intermediate part being liquefied only after prolonged irradiation with high energy.

A more or less regular structure—dark brown/yellowish brown—is often observed, reminding one of the stationary wave patterns previously described.<sup>9</sup> Effective cavities may to some extent be formed here also in the middle part of the tube; occasionally some of the darker spots grow rapidly, and then a gas bubble (due to degassing) will always be seen moving about in a liquefied zone, just as in the case of aluminium oxide gel, where, in the absence of formation of stationary waves in short columns, gas bubbles are driven to the surface, owing partially to radiation pressure, partially to their buoyancy.

**Experiments under gas pressure** were also carried out in long tubes, the external pressure of compressed gas being applied from a cylinder of compressed air. On irradiating now, even with high energy, nothing happens, except a slight movement of the meniscus; this does not cause true liquefaction, except perhaps in a thin upper layer. After prolonged irradiation this upper layer becomes slowly saturated with gas and liquefaction takes place in a narrow zone, the bulk of the gel being absolutely unaffected. When the pressure is turned off, liquefaction begins at once, cavitation now being possible.

These experiments show that the liquefaction of thixotropic gels occurs under exactly the same conditions as where emulsification is observed, *i.e.*, when cavitation (as defined in an earlier paper) is possible. Without cavitation the sound waves cannot even destroy the very weak structure of thixotropic gels.

These experiments show also that the particles of the gels investigated are too small to scatter any appreciable energy, since otherwise stationary wave patterns<sup>9</sup> ought to appear; the gel behaves as a homogeneous medium.<sup>10</sup> Foreign particles, *e.g.*, of quartz of several  $\mu$  diameter, which are big enough to scatter sufficient energy to be affected individually, form stationary wave patterns in these gels just as in liquids.<sup>11</sup>

\* W. R. Wood and A. L. Loomis, *Phil. Mag.*, (7) 1927, 4, 417.

<sup>8</sup> K. Söllner and C. Bondy, *l.*

<sup>9</sup> Some phenomena observed in gel-like systems with particles large enough to be moved individually by the sound waves will be described shortly.

<sup>11</sup> The velocity of sound in these gels is nearly the same as in the medium of dispersion.

## 2. The Peptising Action of Ultrasonics.

In the peptisation of gels by ultrasonics<sup>12</sup> exactly the same result is obtained: neither *in vacuo* nor under a sufficiently high external pressure (so long as the system is not saturated with gas) is peptisation observed.

A sheet of commercial gelatine was rolled together and pushed to the bottom of a test tube, so that it could not be moved by the radiation pressure, when irradiated; then water was added. Three samples were thus prepared: the first (a) was left in that condition, the second (b) was carefully degassed and sealed off, and the third (c) was partially degassed to remove at least all gas bubbles adhering to the gelatine and then connected (with a high column of water on the top) to a cylinder of compressed gas, under a pressure of several atmospheres.

The three tubes were irradiated with medium energy; the gelatine foil in tube (a) started to collapse after 10 to 20 seconds, formed a voluminous clod, and was peptised entirely after about 40 to 60 seconds, the whole process being more rapid with higher energies. In the other two tubes, even after several minutes of irradiation and on applying high energy, the gelatine foils were quite stiff and unaffected, the water remaining quite clear.

Obviously the rate of swelling of suitable substances is much increased when peptisation occurs on irradiation.

Substantially the same result was obtained with many other substances, *e.g.* glue, rubber in different organic liquids, aluminium oxide in dilute HCl, so long as the adherent and enclosed gas is removed, when experimenting *in vacuo* or under pressure, a condition not always too readily fulfilled in the case of gels.

When combining the above facts with the results of many earlier investigations,<sup>13</sup> one may conclude that all the destructive and disruptive effects in non-metallic systems (also in biological systems) reported by many authors must be attributed to cavitation, as defined in an earlier paper.<sup>7</sup>

Mention may also be made of two further points of importance in the peptisation of gels: the vigorous movement to be seen in two-phase systems when irradiated, and the heat developed.

The movement of suspended particles and the stirring effects due to large interfaces in heterogeneous systems were described in an earlier paper<sup>8</sup> and the results obtained there may be applied accordingly to the peptisation.

When a liquid is irradiated, heat is always developed, particularly in the presence of large interfaces.<sup>12</sup> This is due partly to the absorption of sound energy (most pronouncedly with very viscous liquids, *e.g.* glycerol), but much sound energy is scattered and thus transformed into heat by interfaces. It seems, however, that cavitation also may play an important rôle.<sup>14</sup> This question still needs more thorough investigation, specially as to how the occurrence of cavitation depends upon the presence of interfaces.

<sup>12</sup> W. R. Wood and A. L. Loomis; <sup>8</sup> H. Freundlich, F. Rogowski and K. Söllner, *Kolloid-Beihfte*.<sup>1</sup>

<sup>13</sup> *E.g.* E. Newton Harvey; <sup>9</sup> C. Bondy and K. Söllner.<sup>7</sup>

<sup>14</sup> This seems to be correlated with the well-known fact that the propagation of sound is much feebler in liquids containing gas, than in gas-free ones.

## Summary:

The liquefaction of thixotropic gels and the peptisation of gels in general by ultrasonic waves are due to the same effect as emulsification in non-metallic systems, *i.e.* they are due to cavitation. If the latter is prevented, either by external pressure or by experimenting *in vacuo*, no liquefaction and no peptisation is observed, when irradiating with ultrasonics.

## ON A MODE OF ACTION OF SOLVENTS ON CHEMICAL REACTION VELOCITY.

BY C. N. HINSHELWOOD.

*Received 23rd April, 1936.*

Two atoms combine stably only in ternary collisions, the rate being determined by the removal of energy from the product. If the rate is written  $PZe^{-E/RT}$ ,  $P$ , though not  $E$ , will vary widely with the efficiency of the final deactivating collision.

This may apply to more complex association reactions, and efficiency of energy removal is, in principle at least, one of the factors concerned in solvent effects.

In a reversible reaction  $XY = X + Y$ ,  $[XY]/[X][Y] = K$  at equilibrium. In the gas phase the dissociation reaction is frequently of an order between the first and the second, the rate being  $k_1[XY][M]/\{1 + (k_2/k_3)[M]\}$  where  $[M]$  is the concentration of that species which activates  $XY$  by collision. Equally commonly, therefore, the association rate must be  $k_1K[X][Y][M]/\{1 + (k_2/k_3)[M]\}$ , to give the correct equilibrium constant. The direct derivation of this expression assumes the collision of  $X$  and  $Y$  to give an activated molecule which may either relapse to  $X$  and  $Y$  at a rate  $k_2a$ , or be deactivated by collisions to give a product at a rate  $k_3a[M]$ . Then

$$k_1'[X][Y] - k_2a[M] - k_3a = 0,$$

whence rate  $= k_3a[M] = (k_2k_1'/k_3)[X][Y][M]\{1 + (k_2/k_3)[M]\}$ .

When  $(k_2/k_3)[M]$  is great compared with unity, the rate becomes independent of  $[M]$  and  $k_2$ : otherwise the rate depends upon the removal of energy from the product.

In a reaction in solution dependence on  $[M]$  would not be evident, since  $M$  would be the solvent and  $[M]$  constant. The rate might nevertheless be determined by the deactivation of the product by solvent molecules. At first sight  $(k_2/k_3)[M]$  might be supposed always great compared with unity. This, however, is not necessary:  $[M]$  is always great, but  $k_2$  might be correspondingly small. The studies of Eucken<sup>1</sup> on the variation of the velocity of sound with frequency have shown that on the average many thousands of collisions may be necessary

<sup>1</sup> Eucken and Jaacks, *Z. physikal. Chem.*, B, 1935, **30**, 85.

before a quantum of vibrational energy is converted into translational energy, and that the facility of transfer from molecule to molecule varies very widely. For example, 47,000 collisions occur before a molecule of carbon dioxide gains or loses a quantum of vibrational energy, while 630 are necessary for a molecule of hydrogen to remove a vibrational quantum from nitrous oxide. Transfer is extremely difficult except when the two colliding molecules exert strong specific forces on one another in virtue of dipoles, ionic charges or unsaturated valencies.

When the action of the solvent depends upon this mechanism we should expect:

(1) The value of  $P$  will vary widely from solvent to solvent. In favourable circumstances it would be possible to find a series of solvents in which changes in the velocity of a given reaction depended almost entirely on  $P$ . Simultaneous changes in  $E$  by different mechanisms are not precluded in general.

(2) In a reaction where a highly polar association product is formed, *e.g.*, in quaternary ammonium salt formation, the Eucken principle suggests that the energy could be most effectively removed from the ionised linkage by a molecule capable of exerting strong forces on it. Thus some rough functional relation between  $P$  and the dipole moment of the solvent might exist.

(3) For a very inert solvent  $k_2[M]$  might be so small that one of the reactants or the product would have to play the part of the deactivating third body. Thus the reaction might become kinetically of a higher order than the second in the inert solvent.

(4) Increase of pressure, in virtue simply of the increased solvent collision number, could cause a considerable increase in  $P$ .

(5) Small additions of an active to an inactive solvent would bring about a *linear* increase in rate.

With regard to (1), the rather wide variation of  $P$  with solvent is evident from data already available in the literature, as for example in the work of Grimm, Ruf and Wolff<sup>2</sup> on the combination of triethylamine and ethyl iodide. The effect of the solvent on  $P$  is still more clearly shown in the reaction of pyridine and methyl iodide<sup>3</sup> where it also appears that any correlation between the dipole moment of the solvent and the reaction rate is by way of  $P$  and not by way of  $E$ . This might be taken as an example of (2).

Examples of (3) are found. The reaction between benzoyl chloride and aniline is bimolecular in benzene, but in hexane, which is very much more inert, it shows marked autocatalysis by the reaction product. The influence of dilution is also quite anomalous, corresponding to a reaction order more nearly of three than of two.<sup>4</sup> The same autocatalytic effect of the polar product is found in the methyl iodide-pyridine reaction in inert solvents, and an anomalous dilution effect with *m*-nitraniline and benzoyl chloride in carbon tetrachloride.<sup>5</sup>

(4) is exemplified by the marked increase in  $P$  found by Gibson, Fawcett and Perrin<sup>6</sup> for the reaction between ethyl iodide and pyridine in acetone, where the increase of  $P$  between one and 8500 atmospheres is of the order of 1000 times, the increase of reaction rate with pressure occurring in spite of an appreciable increase in the activation energy.

<sup>2</sup> *Z. physikal. Chem.*, **B**, 1931, **13**, 299.

<sup>3</sup> Unpublished experiments of N. J. T. Pickles.

<sup>4</sup> Grant and Hinshelwood, *J. Chem. Soc.*, 1933, 1351.

<sup>5</sup> *Proc. Roy. Soc.*, **A**, 1935, **150**, 223.

(5) is exemplified by the addition of nitrobenzene to benzene in which the reaction of benzoyl chloride and aniline occurs.<sup>6</sup> There is an increase in velocity proportional to the concentration of the two reactants and to that of the nitrobenzene.

It is not suggested that the removal of energy by the solvent molecules is a rate determining factor in general. All the examples quoted are of reactions where a polar salt is formed, and which show about the smallest values of  $P$  ever found. All the individual observations could be given alternative explanations, yet, taken together in the light of general considerations about the specificity of energy transfer, they lend some degree of significance to the question whether this function of the solvent has hitherto been taken fully enough into account. Those conditions where it is likely to be of importance are where there is difficulty about the dissipation of the activation energy into parts of the molecule remote from the active centre. There is evidence that such resistance to internal energy conversion plays a part in other kinetic phenomena.<sup>7</sup>

## REVIEW OF BOOK.

**The Theory of Emulsions and their Technical Treatment.** By WILLIAM CLAYTON. (London: J. & A. Churchill (1935). Pp. 458. 25.5 cms.  $\times$  16 cms. Price 25s.)

The first edition of Clayton's book appeared in 1923, and contained 160 pages; this third edition has nearly trebled its size. The book has developed from an excellent introduction concerning our knowledge of emulsions into an even better text-book of this subject. The very large technical literature on emulsions has been incorporated, and one finds an equally thorough treatment of emulsifiers, colloid mills, homogenisers and the manifold devices used for de-emulsification, on the one hand, and of inversion of emulsions, multiple emulsions, Mudd's interface technique, etc., on the other. Emulsions are complex systems, and any one-sided theory of their stability which excludes all others is unlikely to be the true one. Clayton is therefore perhaps right in discussing the possible explanations so impartially that one often does not know which of them he considers the most probable.

H. F.

## TWO INORGANIC COMPLEXES HAVING IN SOLUTION AN EXCEPTIONALLY HIGH VERDET CONSTANT.

BY RENÉ LUCAS AND FERNAND GALLAIS.

*Received 16th April, 1936.*

As long ago as 1886 Cornu and Potier,<sup>1</sup> studying the influence of the angle of the magnetic field and of the luminous ray on magnetic rotation, made use of "Thoulet liquor" which has a magnetic rotatory power three times greater than that of carbon bisulphide. Several subsequent measurements have confirmed the exceptional position of this solution and it always holds first place amongst the liquids having a high Verdet constant.<sup>2, 3</sup>

One of us having utilised this property for determining the chemical constitution of dilute solutions of alkali iodomercurates,<sup>4</sup> we have resumed the study of such solutions. We have shown that their main constituent, a salt of  $H_2HgI_4$  has an exceptional specific magnetic rotatory power and dispersion, which we have sought to interpret on the grounds of luminous absorption.<sup>5</sup> We were led, later, to investigate the analogous properties of solutions of alkali iodobismuthates.

Recent work having involved the preparation of saturated solutions of complex salts, both of iodomercurates and iodobismuthates of potassium, we hoped to obtain liquids having an exceptionally high magnetic rotatory power. These are the subject of the present communication.

### 1. Preparation of Solutions.

The two solutions in question were adopted after several investigations of other less favourable ones; their composition was thus chosen so that they would have a maximum content of complex salts.

**Saturated Potassium Iodomercurate Solution.**—Pernot<sup>6</sup> determined the solubility isotherms of the system  $HgI_2 + KI$  in water at different temperatures. The proportions of the two iodides used are approximately those of a saturated solution of  $HgI_2$ ,  $KI$ ,  $H_2O$  at 20° C. and, indeed, our solution contains some characteristic crystals of this complex, although it goes without saying that these crystals may differ from the complex anions existing in solution.

*Composition:*  $KI$  9.25 gm.      *Density:*  $d_4^{19}$  3.16.  
 $HgI_2$  12.75 gm.  
 $H_2O$  3.00 gm.

<sup>1</sup> A. Cornu and A. Potier, *Comptes rend.*, 1886, 102, 385.

<sup>2</sup> O. Schönrock, *Z. physik. Chem.*, 1893, 11, 782.

<sup>3</sup> L. R. Ingersoll, *J. Opt. Soc. Am.*, 1922, 6, 663.

<sup>4</sup> F. Gallais, *Comptes rend.*, 1935, 200, 836; 1936, 202, 54.

<sup>5</sup> R. Lucas and F. Gallais, *Comptes rend.*, 1936, 202, 129.

<sup>6</sup> Mlle. M. Pernot, *ibid.*, 1927, 185, 950.

**Saturated Solution of Potassium Iodobismuthates.**—Delwaulle<sup>7</sup> worked out the solubility isotherms of the system  $\text{BiI}_3 + \text{KI}$  in water. The proportions of the two iodides used are approximately those of a saturated solution of the two salts  $\text{BiI}_3$ ,  $\text{KI}$ ,  $\text{H}_2\text{O}$  and  $\text{BiI}_3$ ,  $2\text{KI}$ ,  $\text{H}_2\text{O}$ ; this will deposit one or other of these salts as the proportion of alkali iodide is slightly diminished or increased. We extrapolated for the temperature  $25^\circ$  the curves given for  $15^\circ$  and  $35^\circ$ . At the temperature of  $20^\circ$  at which we worked a fair number of crystals were deposited from the solution.

*Composition* :  $\text{KI}$  5.0 gm.  
 $\text{BiI}_3$  5.90 gm.  
 $\text{H}_2\text{O}$  2.60 gm.  
 $\text{HCl}$  one drop.

*Density* :  $d_4^{10}$  2.54.

The preparation of the two solutions presents no difficulty; the iodides dissolve readily together in both cases on slightly warming the mixture of the three constituents.

## 2. Experimental.

We used for our measurements light from a mercury or cadmium arc of wave-length  $\lambda$  0.6438  $\mu$ , 0.5780  $\mu$ , 0.5461  $\mu$  and 0.4662  $\mu$ . The two solutions being highly coloured (yellow for mercuriiodides and red for bismuthiiodides) and absorbing considerably in the blue and green respectively, we examined them in thicknesses of 5 or even 1.07 mm. The two vessels were placed between the poles of an electromagnet which, with a current of 14 amps. had a magnetic field of about 14,600 gauss per cm. The analyser permitted accurate measurement to one-hundredth of a degree; but, if the double rotation observed for the solutions varied from  $19$  to  $51^\circ$ , the results obtained with water are much less pronounced— $3.33^\circ$  for a thickness of 5 mm., and  $0.79^\circ$  for 1.07 mm. so that, specially in the latter case, the Verdet constants are only known to within 2 or 3 per cent. in relative values. The results are shown in Table I. It will be seen that by using

TABLE I.

Wavelength (in $\mu$ ).	Double Rotation, Observed for a Magneto-Optical Field of		Verdet Constant at $20^\circ$ .	
	1546 gauss/cm. (1.07 mm.).	7345.5 gauss/cm. (5 mm.).	Observed.	Related to that of Water.
<b>A. Potassium Iodobismuthates.</b>				
0.6438 (red)	—	$51.28^\circ$	0.209	—
0.5780 (yellow)	$19.89^\circ$	—	0.386	28.3
<b>B. Potassium Iodomercurate.</b>				
0.6438 (red)	—	$27.37^\circ$	0.112	—
0.5780 (yellow)	—	$38.14^\circ$	0.156	11.4
0.5461 (green)	—	$46.20^\circ$	0.189	12.3
0.4662 (blue)	$19.15^\circ$	—	0.370	17.7

the iodobismuthate solution from red to yellow and iodomercurate from yellow to blue one can obtain magnetic rotations from 18 to 28 times greater than those of water.

<sup>7</sup> Mlle. M. L. Delwaulle, *Comptes rend.*, 1934, 199, 948.

**Summary.**

1. Having studied the exceptional magnetic rotatory power of solutions of iodo-mercurates we now put on record the same characteristics of iodo-bismuthate solutions.

2. Solutions of two complexes giving a maximum rotatory power were prepared, advantage being taken of the known solubility isotherms of the systems  $\text{HgI}_2 + \text{KI}$  and  $\text{BiI}_3 + \text{KI}$  in water.

3. Saturated solutions were thus obtained of complex salts having a specific rotatory power 18 to 28 times greater than that of water.

## OXIDATION-REDUCTION POTENTIALS IN NON-AQUEOUS SOLUTIONS. PART II.

BY J. R. PARTINGTON AND J. W. SKEEN.

*Received 2nd April, 1936.*

The present communication is an extension of the work described in Part I.<sup>1</sup> to other systems and to other solvents such as acetonitrile, benzonitrile and acetone. These solvents and pyridine are of interest from the point of view of the mechanism of the formation of a potential at an oxidation-reduction electrode since they do not ionise to give hydrogen or hydroxide ions.

One series of measurements has been made in anhydrous acetic acid and although this solvent ionises to give hydrogen ions, the results are nevertheless interesting on account of the investigations of von Hevesy and Zechmeister.<sup>2</sup> They found from measurements with lead acetate and lead tetra-acetate in acetic acid with the help of a radio-active indicator that an electrolytic oxidation can take place through a direct transfer of charge. Equimolecular amounts of radio-active plumbic acetate and ordinary plumbous acetate (or *vice versa*) were dissolved in acetic acid followed by separation of the two lead salts after a short time. A uniform distribution of lead isotopes between the plumbic and plumbous compounds was found to occur between the molecules and it was concluded that a dynamic equilibrium was set up between the plumbic and plumbous ions according to the scheme:

If an electrode is present in the system it could participate in the transfer of charges. These authors point out, however, that this is not the only mechanism possible, and that electrolytic oxidations or reductions may take place in some cases through the participation of the solvent.

### Experimental.

**Preparation of Materials.**—(See also Part I.)

**Cupric Bromide** was prepared by treating A.R. copper with a slight excess of A.R. bromine in the presence of a little water, as recommended

<sup>1</sup> Partington and Skeen, *Trans. Faraday Soc.*, 1934, **30**, 1062.

<sup>2</sup> Von Hevesy and Zechmeister, *Z. Elektrochem.*, 1920, **26**, 151.

by Richards.<sup>3</sup> It was kept in a vacuum desiccator over phosphorus pentoxide.

**Cuprous Bromide.**—A warm dilute solution of cupric bromide, prepared as above, was reduced by sulphur dioxide. The cuprous bromide was kept in the dark in a vacuum desiccator over phosphorus pentoxide.

**Cupric Thiocyanate** was obtained by taking a moderately concentrated air-free solution of A.R. potassium thiocyanate acidified with a little sulphuric acid and adding immediately the calculated quantity of a concentrated air-free solution of A.R. copper sulphate. The black precipitate was quickly filtered off, washed with a little air-free water, pressed between filter papers and dried in a desiccator over sulphuric acid.

**Cuprous Thiocyanate** was prepared by reducing a solution containing the appropriate amounts of copper sulphate and potassium thiocyanate with sulphur dioxide.

**Lead Tetra-acetate** prepared by adding red lead slowly to a mixture of acetic acid and acetic anhydride at 55°-65°, was recrystallised from a mixture of the acid and anhydride, washed with cold acetic acid and dried in a desiccator over sulphuric acid.

**Anhydrous Lead Acetate.**—A.R. lead acetate was recrystallised three times from conductivity water containing a little acetic acid. The crystals were dehydrated by leaving in a vacuum desiccator over phosphorus pentoxide.

**Lithium Acetate.**—Pure lithium carbonate was treated with a slight excess of dilute (1 : 1) acetic acid. The solution when evaporated set to a jelly which crystallised overnight. It was recrystallised twice from redistilled 96 per cent. alcohol, dried at 100°, and kept in a vacuum desiccator over phosphorus pentoxide.

## Purification of Solvents.

**Pyridine.**—In the purification described in Part I., it is advisable to reflux the pyridine with a small quantity of potassium permanganate after the initial fractionation. The pyridine was then distilled and the refluxing with barium oxide followed as usual.<sup>4</sup> Commercial barium oxide was suitable if the following procedure was adopted. After the initial fractionation the pyridine was refluxed for six hours with a mixture of barium oxide and potassium permanganate. After distillation it was refluxed with a fresh quantity of barium oxide. It was then finally fractionated from a little barium oxide in an atmosphere of dry nitrogen.

The procedure of keeping and using the solvents described in Part I. was adopted. As the solvents were to be used for solutions of substances such as ferrous chloride and cuprous chloride which are easily oxidised, air was prevented from dissolving in the pure solvent and the last fractionation was done in an atmosphere of dry nitrogen.

**Acetonitrile** was purified by shaking with half its volume of water and then adding solid potassium carbonate until no more dissolved; after separating, the acetonitrile was allowed to stand over a little solid caustic potash for a day, then decanted and allowed to stand over calcium chloride for a week. After distillation it was allowed to stand over a little phosphorus pentoxide for a day. If the first lot of phosphorus pentoxide liquefied it was replaced by some fresh pentoxide until it remained as a lumpy white powder. The liquid was then fractionated in an atmosphere of dry nitrogen with a 12-pear column using the usual precautions to keep out moisture. After standing over some fresh phosphorus pentoxide it was again fractionated in an atmosphere of dry nitrogen and the fraction boiling at 81.5° C. at 760 mm. was collected in the stock bottle. The density found

<sup>3</sup> Richards, *Proc. Amer. Acad.*, 1890, **25**, 206; *Chem. News*, 1891, **63**, 20.

<sup>4</sup> Mathews and Johnson, *J. Physical Chem.*, 1917, **21**, 294.

was  $\Delta_4^{25^\circ} = 0.7767 \pm 0.0001$ . The International Critical Tables (Vol. III., p. 28) give  $\Delta_4^{25^\circ} = 0.7770$ .<sup>5</sup>

**Benzonitrile** was steam distilled and the distillate extracted with ether. The ethereal layer was washed with dilute caustic soda solution and then with dilute sulphuric acid. The product was then allowed to stand over calcium chloride for a few days. After removing the ether on a water-bath it was fractionated under reduced pressure (b.-pt.  $120^\circ$  C. at 10 cm.) using a 25 cm. Hempel column. The middle fraction was left for a day over a little phosphorus pentoxide and then again fractionated under reduced pressure from a little fresh pentoxide. Nitrogen was used to fill the apparatus and also when the pressure was raised. The density found was  $\Delta_4^{25^\circ} = 1.0008 \pm 0.0001$ . The value given in the International Critical Tables (Vol. III., p. 28) is  $\Delta_4^{25^\circ} = 1.0005 \pm 0.0003$ .

**Acetone** was dried by means of anhydrous potassium carbonate.<sup>6, 7, 8, 9</sup> Acetone (Griffin and Tatlock's A.K.) was allowed to stand over potassium permanganate for 24 hours with occasional shaking. After distillation it was left for a few days with occasional shaking over anhydrous potassium carbonate previously dehydrated at  $200^\circ$ – $300^\circ$  C. for several hours. The acetone was then fractionated using a 75 cm. Hempel column in dry nitrogen, being protected from the atmosphere by calcium chloride and soda-lime tubes. This fractionation from potassium carbonate was carried out two more times, a good deal of the first and last fractions being neglected. The acetone used boiled at  $56.3^\circ$  C. at 760 mm. and had a density of  $\Delta_4^{25^\circ} = 0.7847 \pm 0.0001$ . Lannung<sup>8</sup> gives  $\Delta_4^{18^\circ} = 0.7921$ ;  $\Delta_4^{32^\circ} = 0.7702$ , which give by interpolation  $\Delta_4^{25^\circ} = 0.7841$ . The interpolated value for  $20^\circ$ , namely,  $\Delta_4^{20^\circ} = 0.7898$  agrees fairly well with the value of Bell and co-workers<sup>6</sup> and Price<sup>10</sup> who give  $0.7908$ . The refractive index for sodium light was found to be  $1.35715$  at  $25^\circ$  C.

**Acetic Acid** was dehydrated by triacetyl borate.<sup>11</sup> Triacetyl borate is an excellent dehydrating agent since it reacts with water to yield acetic acid and insoluble boric acid: it was prepared according to the directions of Pictet and Geleznoff.<sup>12</sup>

A.R. acetic acid (Griffin and Tatlock) was refluxed with the triacetyl borate and then carefully fractionally distilled using a Hempel column: 2 of 4 times the amount calculated to react with the water present was used. The fraction boiling at  $117.0^\circ$  C. (760 mm.) was collected. Bousfield and Lowry<sup>13</sup> give the boiling-point as  $117.88^\circ$  C.  $\pm 0.05^\circ$  at 760 mm. and the freezing-point as  $16.60^\circ$  C.  $\pm 0.005^\circ$ . Eichelberger and La Mer give the freezing-point as  $16.60^\circ$  C.  $\pm 0.01^\circ$ . The freezing-point of the product used was  $16.59^\circ$  C.  $\pm 0.01^\circ$ .

## Apparatus and Procedure.

To prevent risk of contamination of the solutions by water, in most cases a reference electrode was used in which the solvent was the same as on the other side of the cell. Thus the reference electrode,  $\text{Ag} | \text{AgCl}$  in pyridine, was used in the case of pyridine solutions. In two cases (solutions in benzonitrile and acetone) suitable reference electrode solutions which could be kept for about 3 or 4 weeks could not be found.

<sup>13</sup> Bousfield and Lowry, *J. Chem. Soc.*, 1911, **99**, 1432.

Here it was necessary to refer the potentials to aqueous solutions and the non-aqueous solutions and the aqueous potassium chloride bridge solution were separated by a ground glass-plug to prevent diffusion. Risk of contamination of the non-aqueous solution by water near the electrode was slight, the taps being kept closed except during actual measurements (Fig. 3, Cell IIa).

FIG. 1.—Cell Ia.

In measurements using acetic acid as solvent, the potentials were referred to the aqueous calomel electrode by a method similar to that described by Conant and co-workers,<sup>14</sup> a saturated solution of lithium acetate in acetic acid being used as bridge solution to separate the aqueous and non-aqueous electrode solutions (Fig. 4, Cell III).

A modification of the cell previously described was used for the pyridine solutions. In this, the connecting tap was reversed (Cell Ia, Fig. 1) in order to facilitate the levelling of the solutions.

In certain cases (where the solvent was acetonitrile) the conductivity of the solutions was good and the two electrode solutions could be separated by a ground-glass plug to prevent diffusion (Cell II, Fig. 2).

All solutions were made up by weight in an atmosphere of dry nitrogen as previously described.

As the solutions used, however, were so dilute that the density did not differ much from that of the pure solvent, the error involved in using the latter figure to calculate the volume of the solution was much less than other experimental errors. The value of the concentration was only necessary in order that a check could be kept on the total concentration of the salts used.

**Preparation of the Electrodes.**—In a few cells gold as well as platinum electrodes were used. Pieces of gold foil approximately 2 cm. by 1 cm. were suspended by being fused on gold wire. This was fused to platinum wire sealed into glass tubing. Connection was made by silver wire fused to the platinum.

FIG. 2.—Cell II.

The 0.1*N*-calomel electrode<sup>15</sup> had a three-way stopcock to enable fresh calomel electrode solution to be run in through the side-arm in place of

<sup>14</sup> Hall and Conant, *J. Amer. Chem. Soc.*, 1927, 49, 3047; Conant and Werner, *ibid.*, 1930, 52, 4436.

<sup>15</sup> Lewis, Brighton and Sebastian, *ibid.*, 1917, 39, 2245.

two separate stopcocks. The mercurous chloride was made electrolytically. The cells were first filled with dry nitrogen.

FIG. 3.—Cell IIa.

**Cell Ia.**—After connecting the right-hand limb and the outlet tube (C) by means of the tap B, the solution was forced over into the right-hand compartment to the level marked on the outlet tube. The tap was then turned round a little way and the small amount of liquid in C was removed by a roll of filter paper. A slight pressure was then established in the left-hand limb by commencing to force over the other solution. On turning the tap B so as to connect this limb and the outlet tube, the small amount of liquid in the bore of the tap was blown into C and was then removed by filter paper. The left-hand limb was then filled to the same level as the mark on C. The excess liquid in C was then removed by a roll of filter paper. The mark on C was so arranged that by this means the correct amount of solution was run into the electrode vessels.

FIG. 4.—Cell III.

**Cell II.**—The right-hand limb as far as the ground-glass plug (F) was first filled by manipulation of the tap E. The left-hand limb and the middle compartment were filled afterwards. Taps D and E were kept closed except during measurements.

**Cell IIa.**—Saturated potassium chloride solution was put in the right-hand limb as far as the ground-glass plug and filling continued as described above. The intermediate apparatus between the actual cell and the calomel electrode was used to separate the saturated and 0.1N potassium chloride solutions.

**Cell III.**—The ground-glass stopper (G) was placed tightly in position and the saturated potassium chloride solution placed in the intermediate vessel. The solution rose just to the top of the stopper. The non-aqueous bridge solution was then run in through the tap H till it just filled the bore of the tap J. The electrode solution was then run in through the tap K. The tap J was opened only while measurements were being made.

FIG. 5.—Series IV.

**Limits of Accuracy.**—Readings were taken to the nearest millivolt in all cases except the systems cupric-cuprous chlorides and cupric-cuprous bromides in acetonitrile where they could easily be measured to a tenth of a millivolt, even when using

the cell with the ground-glass plug. Actually, the latter system was seldom measured to less than a millivolt, as the potentials varied rapidly. The electromotive forces were measured at 25° C., the cell being in an air thermostat.

## Results.

**Series IV.**—Cell Ia used (Table I, Fig. 5). Equilibrium was established almost immediately and the electromotive force remained constant for at least an hour—for eight of the cells it remained constant for about three hours. It then slowly decreased.

A solution of cupric bromide in pyridine decomposes and the system  $\text{CuBr}_2/\text{CuBr}$  could not be measured.

*Series V.*—Cell II used (Table II., Fig. 6). An oxidation-reduction system itself was used as a reference electrode (shown on the right) and the solution was stable throughout the whole series of measurements. Equilibrium was established almost immediately; the E.M.F., after remaining constant to within a tenth of a millivolt for about an hour, slowly decreased; it remained constant to within a millivolt for more than 5-6 hours. In the cells in which the

FIG. 6.—Series V.

concentration of cupric chloride was over 90 per cent., however, the E.M.F. fell continuously.

The effect of dilution on a solution in which the concentration ratio was kept constant was measured.

+ Pt $\left  \begin{array}{l} \text{Stock Solution.} \\ \text{Total Concentration} \\ = 0.06482 \text{ M.} \end{array} \right $		$\left  \begin{array}{l} \text{Diluted Stock Solution.} \\ \text{Total Concentration} \\ = 0.04548 \text{ M.} \end{array} \right $		Pt -.
---	--	--	--	-------

E.M.F. = 2.7 millivolts.

Further dilution to about 0.022 M. increased the potential to 6.5 millivolts. Thus, the effect produced on the electromotive forces of the cells measured by not using solutions of exactly the same total concentration throughout was negligible when compared with differences of potential produced by variation of the concentration ratio.

In a few preliminary measurements an attempt was made to use the reference electrode copper/copper chloride in acetonitrile as in the case of pyridine (Series I). This was discontinued as the green solution of cupric chloride in acetonitrile turned brown in about half an hour in contact with a copper electrode which was also blackened just as in the case of the measurements with pyridine.

Series VI. Cell II used.

+ Pt $\left  \begin{array}{l} \text{CuBr}_2 \\ \text{CuBr} \end{array} \right $ in acetonitrile.		$\text{CuBr}_2$ (0.02427 M.) $\text{CuBr}$ (0.02426 M.) in acetonitrile.		Pt -.
--	--	---	--	-------

Reference Electrode.

The results obtained were in all cases smaller than the theoretical E.M.F. but were usually approximately constant for about three hours.

Measurements of this series were also made with the reference electrode

Pt $\left  \begin{array}{l} \text{CuCl}_2 \\ \text{CuCl} \end{array} \right $ in acetonitrile which was used in the previous series and found to be stable.	
---	--

Series VII. Cell II used.

+ Pt $\left  \begin{array}{l} \text{CuBr}_2 \\ \text{CuBr} \end{array} \right $ in acetonitrile.		$\text{CuCl}_2$ (0.02322 M.) $\text{CuCl}$ (0.02285 M.) in acetonitrile.		Pt -.
--	--	---	--	-------

Reference Electrode.

Measurements were made with both platinum and gold electrodes but the potentials were not steady. The potential with the gold electrode was initially 0.05 volt more negative than that with the platinum, but this difference fell to 3 to 10 millivolts after about three hours. Addition of a little cupric chloride as a potential mediator had no effect. Changes of colour in the solutions in all cases indicated decomposition.

*Series VIII.* Cell IIa used.

Difficulty was experienced in getting the ferrous chloride to dissolve. Owing to this, and also to the fact that extremely dilute solutions had to be used, the values obtained were probably not equilibrium values, although in nearly every case the potential remained constant for about an hour.

The solubility of cupric chloride appeared to be too small to allow measurement of the system  $\text{CuCl}_2/\text{CuCl}$  to be made.

Although both ferric and ferrous chlorides are soluble in acetonitrile no measurements could be made with this pair of salts as a solution of the two decomposed within an hour.

*Series IX.* Cell IIa used (Table III., Fig. 7). Although the solutions were made up just before the cell was filled

they gradually decomposed during the measurement, so that the values given can be regarded as approximate only. Reference electrodes using acetone as solvent:

c.g. Ag/AgCl (s), saturated LiCl in acetone,  
and Hg/Hg<sub>2</sub>Cl<sub>2</sub> (s), saturated LiCl in acetone.

were not used, since (1) solutions of ferric chloride and lithium chloride in acetone react to give an orange precipitate; (2) mercurous chloride in

indefinite results. The gold electrode was least affected by washing with alcohol and heating in a flame.

In order to compare some of the results with those of Abegg and Neustadt,<sup>18</sup> in two other cases, namely, the systems CuCl<sub>2</sub>/CuCl in acetonitrile and Cu(CNS)<sub>2</sub>/CuCNS in pyridine, the potentials were referred to aqueous solutions using the same method as employed in series VIII. and IX. (Cell IIa). The first cell measured was ([CuCl<sub>2</sub>]/[CuCl] = 1) :

+ Pt	CuCl <sub>2</sub> CuCl	in acetonitrile.	Satd. aq. KCl.	Aqueous 0.1N. calomel.	Hg—.
$e_1$			$e_3$		$e_2$

$$E = e_1 - e_3 + e_2 = 0.565 \text{ volt.}$$

Taking  $e_3 = 0.333$  (value for 0.1N calomel at 25° C., the liquid junction potential between the saturated and 0.1N potassium chloride solutions being negligibly small) and neglecting the liquid junction potential between the aqueous and non-aqueous solutions, we find :

$$e_1 = E_0 + \frac{RT}{F} \log_e \frac{[\text{CuCl}_2]}{[\text{CuCl}]} = 0.898.$$

$$\therefore E_0 = 0.898, \text{ since } \log \frac{[\text{CuCl}_2]}{[\text{CuCl}]} = 0.$$

$\text{Cu}^{++} - \text{Cu}^+$

This is the value of the normal oxidation-reduction potential of the system CuCl<sub>2</sub>/CuCl in acetonitrile if we assume the liquid junction potential is negligible and the ratio of the activities of the cupric and cuprous ions is equal to the ratio of the concentrations of the salts.

<sup>18</sup> Abegg and Neustadt, *Z. Elektrochem.*, 1909, **15**, 264.

The other cell measured ( $[\text{Cu}(\text{CNS})_2]/[\text{CuCNS}] = 1$ ) was :

$$E = e_1 - e_2 + e_3 = 0.050.$$

Whence

$$E_0 = 0.383.$$

This is close to Abegg and Neustadt's value of 0.37 volt for the system  $\text{CuCl}_2/\text{CuCl}$  in pyridine, although the agreement is fortuitous. Thus, the value of  $E_0$  for the system  $\text{CuCl}_2/\text{CuCl}$  in pyridine, although it has not been measured in the present research, is on the assumptions made above about 0.28 volt, about 0.10 volt less than that of the  $\text{Cu}(\text{CNS})_2/\text{CuCNS}$  system. The reference electrodes in the two series were nearly the same and the electromotive forces of the former were found to be about 0.10 volt less than those of the second system. These various values differ considerably from the value of  $E_0$  for aqueous solutions, namely 0.16 volt.

Abegg and Neustadt's conclusion that the normal oxidation-reduction potential was the same in pyridine as in water does not seem to be correct. Some of the difference may be accounted for by the different degrees of dissociation of the salts in the non-aqueous solutions and also by some error probably made in neglecting the liquid junction potential.

The following approximate solubilities at 25° C. were determined to complete the data on the solubilities of the salts employed.

*Pyridine.* Cupric thiocyanate, 0.045*M*. Cuprous thiocyanate contains more than 20 gms. per litre.

*Benzonitrile.* Anhydrous ferrous chloride, 0.012*M*.

*Acetone.* Anhydrous ferrous chloride, 0.147*M*. Potassium ferricyanide is insoluble.<sup>17</sup>

*Acetic acid.* Lead tetra-acetate, 0.075*M*. Anhydrous lead acetate, 2.03*M*. Lithium acetate approximately 1.83*M*.

### Discussion.

The electromotive force of the cell :

can be expressed by the equation (Peters' formula) :

$$E = E_0' + \frac{RT}{nF} \log_e \frac{[\text{Oxidised form}]}{[\text{Reduced form}]}$$

$E_0'$  is a constant which includes the potential of the reference electrode, the liquid junction potential (assumed to remain constant), and the normal oxidation-reduction potential of the system. On the assumption that the ratio of the activities of the ions of oxidised and reduced forms is equal to the ratio of the concentrations of oxidised and reduced salts, the logarithm of this ratio (as abscissa) plotted against  $E$  (as ordinate) should approximate to a straight line. When the potentials were definite the only exception found was the system  $\text{CuCl}_2/\text{CuCl}$  in acetonitrile.

<sup>17</sup> Cf. Naumann, *Ber.*, 1904, **37**, 4328.

$E$  has also been plotted against the percentage concentration of the oxidised form. When due regard is had to the approximate assumptions involved in the equation, the agreement with similar curves for aqueous solutions is very good, especially in series IV, in which pyridine was the solvent. Series VIII. showed qualitative agreement with the equation, but owing to the small solubility of the ferrous chloride the lower part of the curve was not very definite. The solutions of ferric and ferrous chloride in acetone (Series IX.) were unstable but qualitative agreement with the formula is shown although the differences in the potentials obtained by varying the concentration ratio are much greater than those predicted by theory. Series X. shows good agreement with the oxidation-reduction equation.

The curves obtained with the cupric-cuprous chloride system in acetonitrile (Series V.) are peculiar. Both curves are fairly symmetrical about the point 50 per cent.  $[\text{CuCl}_2]$  — 50 per cent.  $[\text{CuCl}]$ , and the one obtained by plotting  $E$  against the percentage concentration of cupric chloride can be considered to be made up of two separate oxidation-reduction curves, one lying between 0 — 50 per cent.  $[\text{CuCl}_2]$  and the other between 50 — 100 per cent.  $[\text{CuCl}_2]$ . The shape of the curve seems to indicate the formation of a compound (or complex ion) from one molecule (or ion) of cupric chloride and one molecule (or ion) of cuprous chloride. A solution of cupric chloride in acetonitrile is pale green and a solution of cuprous chloride is practically colourless or very pale amber, whereas a solution of the two is brown, the colour being deepest when they are present in equimolecular proportions. This compound has been reported to be doubtfully present in various solutions.<sup>18</sup>

If this compound exists in the solutions in acetonitrile, there will be oxidation-reduction reactions between it and the simple salts. If the salt present in concentration lower than 50 per cent. combines completely with an equal number of molecules of the salt present in the higher concentration, then in such a solution there will really be the same number of molecules of complex as there were originally of salt in the lower concentration, and the excess of the other salt molecules.

Let the solution contain  $x$  per cent. of the oxidised form ( $\text{CuCl}_2$ ) and  $(100 - x)$  per cent. of the reduced form ( $\text{CuCl}$ ). Two cases must be considered, viz. (1)  $(100 - x) > x$ , and (2)  $x > (100 - x)$ .

In case (1) the cuprous salt will be in excess. There will be  $(100 - 2x)$  per cent.  $\text{CuCl}$  left, since approximately  $x$  per cent. has combined with the  $x$  per cent. of  $\text{CuCl}_2$  to form  $x$  per cent. of complex, and there will be practically no  $\text{CuCl}_2$  left. In case (2) practically all the  $(100 - x)$  per cent.  $\text{CuCl}$  will combine with an equal amount of  $\text{CuCl}_2$  to form approximately  $(100 - x)$  per cent. of complex, and there will be  $\{x - (100 - x)\} = (2x - 100)$  per cent.  $\text{CuCl}_2$  left. If the complex ion is assumed to be  $\text{Cu}_3^{+++}$ , the charge difference as compared with  $\text{Cu}_2^{++}$  and  $2\text{Cu}^+$  is in each case unity ( $y = 1$ ).

Thus, in the range 0 — 50 per cent.  $[\text{CuCl}_2]$ , we have an oxidation-reduction relation between the cuprous salt and the complex, the latter giving the higher valency ion, and in the range 50 — 100 per cent.  $[\text{CuCl}_2]$  one between the complex and the cupric salt in which the latter now gives the higher valency ion. The normal oxidation-reduction potential of the latter system must be greater than that of the former to give the correct shape of the curve.

<sup>18</sup> Kohlschütter, *ibid.*, 1904, 37, 1153.

$$E = E_0 + \frac{RT}{yF} \log_e \frac{[\text{Oxidised form}]}{[\text{Reduced form}]}$$

Case (1)  $E' = E_0' + \frac{RT}{yF} \log_e \frac{x}{(100 - 2x)},$

or  $E' = a' + b' \log \frac{x}{(100 - 2x)}$  where  $a$  and  $b$  are constants.

Case (2).  $E'' = a'' + b'' \log \frac{(2x - 100)}{(100 - x)}.$

The values of  $a$  and  $b$  were found by taking two points on the curve (marked by asterisks in the table) and the equation checked with other points. The agreement is fairly good (Table V.).

TABLE V.

0 - 50 per cent. [CuCl <sub>2</sub> ].			50 - 100 per cent. [CuCl <sub>2</sub> ].		
$E' = -0.116 + 0.0694 \log \frac{x}{(100 - 2x)}.$			$E'' = 0.155 + 0.120 \log \frac{(2x - 100)}{(100 - x)}.$		
Per Cent.	E.M.F. (Obs.).	E.M.F. (Calcd.).	Per Cent.	E.M.F. (Obs.).	E.M.F. (Calcd.).
0	—	∞	60	0.119	0.119*
10	-0.179	-0.179*	70	0.175	0.170
20	-0.150	-0.149	75	0.192	0.191
25	-0.135	-0.137	80	0.212	0.212*
30	-0.125	-0.125*	90	0.252	0.263
40	-0.085	-0.095	100	—	∞

The results cannot be easily explained as entirely due to the effect of dilution on the dissociation of the two simple salts.

Thus, at the point 10 per cent. [CuCl<sub>2</sub>], let  $\alpha'_{10}$  be the degree of dissociation of the CuCl<sub>2</sub> of concentration  $c'_{10}$ , and  $\alpha''_{90}$  the degree of dissociation of the CuCl of concentration  $c''_{90}$ .

Similarly at the point 90 per cent. [CuCl<sub>2</sub>], let  $\alpha'_{90}$  be the degree of dissociation of the CuCl<sub>2</sub> of concentration  $c'_{90}$ , and  $\alpha''_{10}$  the degree of dissociation of the CuCl of concentration  $c''_{10}$ .

Then  $E_{10} = -0.179 = E'_0 + \frac{RT}{F} \log_e \frac{\alpha'_{10} \cdot c'_{10}}{\alpha''_{90} \cdot c''_{90}}$

and  $E_{90} = 0.252 = E'_0 + \frac{RT}{F} \log_e \frac{\alpha'_{90} \cdot c'_{90}}{\alpha''_{10} \cdot c''_{10}}$

Whence  $\frac{\alpha'_{90}}{\alpha'_{10}} \bigg/ \frac{\alpha''_{10}}{\alpha''_{90}} = 2.41 \times 10^3$

Suppose on dilution from 90 per cent. to 10 per cent. ( $c'_{90} - c'_{10}$ ) the degree of dissociation of the CuCl<sub>2</sub> ( $\alpha'_{90} - \alpha'_{10}$ ) is affected to approximately the same extent as that of the CuCl ( $\alpha''_{90} - \alpha''_{10}$ ) on dilution from 90 per cent. to 10 per cent. ( $c''_{90} - c''_{10}$ ), then the above ratio indicates that *dilution* of the CuCl<sub>2</sub> and also of the CuCl approximately 9 times over similar concentration ranges would *decrease* the degree of dissociation of each by approximately 500 times.

### Summary.

Peters' formula can be applied quantitatively to several oxidation-reduction systems in stable non-aqueous solutions : in a few cases unknown complex formation may occur giving potentials which do not agree directly with the equation but are definite, reproducible, and appear to follow a modified form of the equation. In certain cases indefinite potentials are given at unattackable electrodes.

The authors express their thanks to the Chemical Society for a grant, and one of them (J. W. S.) is indebted to the Department of Scientific and Industrial Research for a maintenance allowance.

## THE MECHANISM OF ELECTROLYTIC PROCESSES. PART III.—IRREVERSIBLE REDUCTIONS.

BY W. M. LESLIE AND J. A. V. BUTLER.

*Received 6th March, 1936.*

Irreversible electrolytic reductions have usually been regarded as secondary reactions between the depolariser and the hydrogen formed at the cathode, but a great variety of behaviour has been found in the numerous investigations which have been made, and it is evident that many of the operative factors are at present unknown. Thus, some substances are reduced only at high overvoltage cathodes and others require low overvoltage cathodes, while in some cases specific effects occur which have been regarded as due to the catalytic action of the metal on the reaction.

The object of the work described here was to attempt to distinguish and identify some of these factors. In general, there are three principal methods by which reduction might be effected :

- (1) by the direct transfer of electrons from the electrode to depolariser ;
- (2) by reaction between the depolariser and free (atomic) hydrogen ;
- (3) by reaction between the depolariser and adsorbed hydrogen.

In order to distinguish these cases it is necessary in the first place to know in what state hydrogen is formed at the electrode. Two distinct types of mechanism for the discharge of hydrogen ions have been proposed :

(A) The primary act is the transfer of electrons from the electrode to hydrogen ions in the solution (*e.g.* Gurney's theory).<sup>1</sup> As Gurney has pointed out, this mechanism is essentially irreversible.

(B) The primary act is the transfer of hydrogen ions from the solution to adsorption places on the electrode, followed by their evaporation as molecular pairs from the surface,<sup>2</sup> *viz.* :

<sup>1</sup> Gurney, *Proc. Roy. Soc., A*, 1931, **134**, 137.

<sup>2</sup> Frumkin, *Acta physicochemica, U.S.S.R.*, 1935, **2**, 505 ; Polanyi and Horiuti, *Z. physikal. Chem.*, *A*, 1933, **164**, 121.

When the metal surface is also in adsorptive equilibrium with the hydrogen atmosphere this process is completely reversible.

We shall take the view, which will be supported in detail in another publication, that at high overvoltage (irreversible) electrodes the process which occurs is of type A, while that at reversible electrodes (platinised or activated platinum, etc.) is of type B. With some metals of low overvoltage, both processes may contribute to the current.

It is probable that adsorbed hydrogen is present on the surface of the metal in both cases, the essential difference between electrodes of the two types being in the rate of desorption. For adsorbed hydrogen can be liberated, on account of its lower potential energy, at a less negative potential than is required by Gurney's mechanism; hence, when a current is passed it is to be expected that adsorbed hydrogen will first be liberated.

The amount of adsorbed hydrogen will continue to increase until either the rate of desorption is equal to its rate of formation, when an equilibrium state will be established and hydrogen will continue to be liberated by mechanism B, or if the rate of desorption is insufficient the surface will become saturated and the potential will rise to the point at which process A can take place. Although it is easy to demonstrate the formation of adsorbed oxygen prior to the establishment of the oxygen overvoltage, the formation of adsorbed hydrogen at metals of high overvoltage has not been experimentally demonstrated, but it is clearly a possibility which must be taken into account.

On these views, it follows that little or no atomic hydrogen is formed at reversible electrodes, and only those reductions can be brought about which are effected by adsorbed hydrogen. At high overvoltage electrodes, the reductions might be effected either by free or adsorbed hydrogen. But if the reaction is a purely secondary one between free hydrogen and the reducible substance, in the absence of disturbing factors the potential of the electrode will be that at which hydrogen is normally liberated in the absence of the substance. But if the substance is adsorbed on the electrode surface, the effective area of the latter may be reduced and the potential thereby displaced in the negative direction. If the reduction occurs at potentials below the hydrogen overvoltage, the process may be effected by either adsorbed hydrogen or by direct electron transfer.

It has frequently been stated that the energy of the liberated hydrogen is greater, the greater the overvoltage at which it is produced. This is only true in the limited sense that free atomic hydrogen has a greater potential energy than adsorbed hydrogen, but in a series of high overvoltage metals it does not appear to be necessary that the potential energy of the hydrogen should be greater the greater the overvoltage, for the latter is the potential difference which is required to raise the electron levels of the metals by a sufficient amount to enable the transfer to take place. It is probable also that adsorbed hydrogen at reversible electrodes is in a more reactive condition than that at inert electrodes at which the rate of desorption is slow.

These distinctions are supported by a broad survey of the facts. Difficulty reducible compounds require a high overvoltage cathode, *i.e.* they are effected by atomic hydrogen. The reduction of unsaturated compounds, on the other hand, is usually more readily brought about at platinised and similar electrodes. For example, the reduction of cinamic acid is small at a bright platinum electrode, but occurs readily at

electrodes coated with nickel or palladium black. This is evidently a case of reaction with adsorbed hydrogen, and it would appear that it only differs from the catalytic hydrogenation in that the hydrogen is produced on the electrode surface.

### Experimental.

These experiments were designed to give illustrative examples of the various types of reduction processes. Some of the cases chosen have already been extensively investigated, but the earlier workers were usually more interested in the products of the electrolysis than the conditions and in many cases very little information is available as to the potentials at which the reduction takes place.

The experimental arrangements were similar to those described in Part II.<sup>3</sup> The solutions were freed from oxygen by bubbling a stream of purified nitrogen or hydrogen. With mercury electrodes it was found that erratic oscillations of the potential occurred unless hydrogen was used and the electrode given a short cathodic polarisation during the introduction of the solution to the cell. The electrodes used had an approximate apparent area of 2 cm.<sup>2</sup> The lead was A.R. (As free) quality, and fresh electrodes were prepared for each set of experiments. The standard electrode was mercurous sulphate in *N* sodium sulphate ( $E_0 = +0.67$ ). In this paper the potentials have been converted to the hydrogen scale.

**Acetone.**—Elbs and Brand<sup>4</sup> found that acetone was reduced at a lead cathode, the reduction products being mainly isopropyl alcohol and pinacol. Under certain conditions, and particularly at cadmium electrodes, propane and metal alkyls can be formed.<sup>5</sup> Hibbert and Read<sup>6</sup> found that the lowering of the cathodic potential produced by acetone was about 0.05 volt. Experiments were made with lead electrodes on *M/10* acetone in *M/10* sulphuric acid, and it was found that the current-potential curve (taken from  $i = 20$  to  $5200 \times 10^{-6}$  amps.) was practically unaffected by the addition of acetone, the depression of the potential amounting at most to 4 millivolts. The reduction of acetone at this electrode is thus a purely secondary process, and is to be regarded as a reaction with atomic hydrogen. The low efficiency of the reduction<sup>6</sup> and the nature of the products are in agreement with this view.

**Sodium Formate.**—At a lead electrode in alkaline solution containing *M/100* formate there was no essential displacement of the current-potential curve, even with very small current, at first, and no sign of concentration polarisation. That reduction occurred was shown by the formation of a white film (probably paraformaldehyde) on the surface of the electrode, which in successive runs caused the potential to be displaced towards more positive values. This reduction is therefore probably also a secondary reaction with atomic hydrogen. Owing to the film formation it was not studied in detail.

**Pyridine** is readily reduced to piperidine in acid solutions at lead and mercury cathodes.<sup>7</sup> The addition of hydrogen carriers which are effective in other reductions has no effect, but it has been found that the presence of colloidal platinum, prepared by Bredig's method and the addition of a small percentage of palladium chloride reduced the current-efficiency at mercury from 40 to 8 per cent.<sup>8</sup>

It was found that at a mercury cathode the current-potential curve (taken from  $i = 13$  to  $1200 \times 10^{-6}$  amps.) was scarcely affected by the

presence of pyridine ( $M/10$ ), so that this reduction is also a secondary one produced by atomic hydrogen. The observations quoted above indicate that the reduction is not brought about by adsorbed hydrogen for the effect of colloidal platinum and the deposition of palladium is to produce an adsorbent surface.

An interesting and novel phenomenon was observed with bright platinum electrodes. Fig. 1 shows the current-potential curves obtained with various concentrations of pyridine in  $M/10$  sulphuric acid. Even

FIG. 1.—Current-potential curves for pyridine in  $M/10$   $H_2SO_4$  at Pt cathode. (1)  $H_2SO_4$  alone; (2) +  $M/10,000$ ; (3) +  $M/1000$ ; (4) +  $M/100$ ; (5) +  $M/10$  pyridine.

very small concentrations of pyridine cause a displacement of the whole curve in the negative direction. This is apparently due to the electrocapillary adsorption of the pyridine on the electrode. No adsorption occurs at mercury, but the potential in this case is considerably more negative than at platinum, and it is known that capillary active substances which are adsorbed on mercury in the neighbourhood of the "null" point are almost completely displaced from the surface at more negative potentials.<sup>9</sup>

<sup>9</sup> Butler, *Proc. Roy. Soc., A*, 1929, 122, 399.

**Nitrobenzene.**—The reduction of nitrobenzene has been extensively studied by Haber and Russ and the former showed<sup>10</sup> that the main reaction occurs in the following successive stages :

Under appropriate conditions side reactions between these intermediates may give rise to azoxybenzene, hydrazobenzene or azobenzene. The reduction takes place at a considerably more positive potential than that at which hydrogen is liberated in the absence of nitrobenzene. Russ<sup>11</sup> investigated the dependence of the potential on the current and concentration of nitrobenzene and his results are referred to in the discussion.

FIG. 2(a).—Current-potential curves for nitrobenzene in  $M/10 \text{ H}_2\text{SO}_4$ ; mercury cathode.

Russ's measurements were made with comparatively concentrated solutions of nitrobenzene in alcoholic solution and in the range of currents used show no transition to a higher potential. When dilute aqueous solutions are used there is a transition current above which the potential rises to the neighbourhood of the hydrogen overvoltage. Fig. 2(a) shows some current-potential curves obtained in  $M/10$  sulphuric acid with a mercury cathode. It has been suggested<sup>12</sup> that in the case of irreversible reductions the transition is not due to the depletion of the depolariser at the electrode,

<sup>10</sup> Haber, *Z. Elektrochem.*, 1898, 4, 506; *Z. physikal. Chem.*, 1900, 32, 271.

<sup>11</sup> Russ, *ibid.*, 1903, 44, 641.

but to the slowness of the reaction between hydrogen and the depolariser (*i.e.* there is a maximum rate of the reaction for a given concentration of

the depolariser, and if the current exceeds this value, hydrogen accumulates at the electrode and causes the potential to rise to the potential at which it is liberated). It has been shown that the transition current is not a very precise quantity and more exact information is obtained from the potential-time curves with constant currents (Fig. 2(b)). These showed transitions of exactly the same type as those obtained in the reversible reduction of hydroquinone, etc., and Fig. 3 shows that they obey the

relation  $it = i_0 t + \alpha$  (where  $t$  is the transition time and  $i_0$  and  $\alpha$  are constants), which has been found to hold for numerous cases in which the

transition is undoubtedly due to concentration polarisation.<sup>13</sup> The constants  $i_0$  and  $\alpha$ , given in Table I., are approximately proportional to

<sup>13</sup> Armstrong and Butler, *Proc. Roy. Soc., A*, 1933, 139, 406.

the concentration of nitrobenzene. The transition in this case is thus probably due to the depletion of the depolariser at the electrode.

It is also to be observed that neither the current-potential nor the time-potential curves show any signs of consecutive processes, which would be the case if any of the primary products of the reduction were reduced at a more negative potential than nitrobenzene. Haber has shown that it is possible by controlling the potential of the electrode to obtain different reduction products. It is unlikely that this is a direct result of the variation of the

potential, although it may arise from secondary effects. For example, if the current employed is above the transition value, so that the potential

is near the hydrogen over-voltage, reduction by atomic hydrogen may occur, for the depolariser will still reach the electrode at the maximum rate of diffusion and may when reduced in this way give rise to different products than those at the lower potential.

**Benzaldehyde.**—The reduction of benzaldehyde <sup>14</sup> also takes place at more positive potentials than the hydrogen overvoltage, but the displacement at mercury is comparatively small. Fig. 4(a) shows the current-potential curves of solutions in *M*/10 sulphuric acid with a mercury electrode. These show a transition, the upper part of the curve being on the right of the hydrogen overvoltage line. This indicates the adsorption of the reduction products on the surface. Notwithstanding the small rise of potential-time curves, examples of which are shown in Fig. 4(b) show a well-defined transition, and the transition times for a given solution are related to the current by  $it = i_0t + \alpha$ , but in this case the constants  $i_0$  and  $\alpha$  were found to be not proportional to the concentration.

### Discussion.

The following cases have been observed : (1) the potential at which electrolysis takes place is unaffected by the reducible substance (acetone and sodium formate at lead, pyridine at mercury) ; (2) electrolysis occurs at potentials more positive than those required for the liberation of hydrogen in the absence of the depolariser (nitrobenzene and benzaldehyde at mercury) ; (3) the substance causes a displacement of the potential in the negative direction. In (1) the process is evidently a purely secondary reaction of the reducible substance with free atomic hydrogen. In (2) there are two possibilities, (a) reaction of the depolariser with adsorbed hydrogen, (b) reduction by the direct transfer of electrons from the electrode to the depolariser. It does not appear to be possible at present to make a definite decision between these two modes.

In the theory of electrolytic reduction proposed by Haber and Russ,<sup>15</sup> which was designed to account for cases of this kind, it was supposed that the depolariser reduced the effective concentration of hydrogen at the electrode and thereby depressed the potential in accordance with the equation

$$E = E^{\circ} + \frac{RT}{F} \log \frac{H^+}{[H]} \quad . \quad . \quad . \quad . \quad (1)$$

where  $[H]$  is the effective concentration of (atomic) hydrogen at the electrode. The concentration of hydrogen is determined by equilibrium between its rate of formation ( $i$ ) and its rate of reaction with the depolariser  $D$ , which taking the stoichiometrical equation of the reaction as  $D + nH \rightarrow DH_n$  was assumed to be  $k[D][H]^n$ . Hence

$$E = E^{\circ} + \frac{RT}{nF} \log \frac{k[D][H^+]}{i}$$

Haber and Russ found that the variations of  $E$  with the concentration of the depolariser and with the current ( $i$ ) was reasonably in accordance with an expression of the type

$$E = E^{\circ} + x \log \frac{[D]}{i}$$

<sup>14</sup> Law, *J. Chem. Soc.*, 1906, 89, 1512 ; 1907, 91, 748 ; 1911, 99, 113.

<sup>15</sup> *Loc. cit.*, ref. (11) ; Haber and Russ, 1904, 47, 257.

when  $x$  has values which are closer to that required for  $n = 1$  than for the stoichiometrical value of  $n$ . For example, in the reduction of nitrobenzene in alkaline solutions at platinum, gold and silver,  $x$  varied from 0.048 to 0.054, and in acid solutions at platinum and gold from 0.053 to 0.075.

Haber and Russ's derivation assumes that the electrode functions as a reversible hydrogen electrode which is certainly incorrect with ordinary smooth electrodes.<sup>16</sup> Now, as has been pointed out, it is possible that adsorbed hydrogen may be formed at potentials below the normal overvoltage which might react with the depolariser in this way, but at an irreversible electrode the potential would not be related to the amount of adsorbed hydrogen by a relation like (1). It is therefore very doubtful whether the Haber and Russ relation would be obtained at an irreversible electrode even if the reduction took place by the formation of adsorbed hydrogen below the normal overvoltage and its reaction with the depolariser.

A relation of the type

$$E = E^\circ + \frac{RT}{F} \log \frac{D}{i}$$

is also to be expected when the process is a direct electron transfer from the electrode to the depolariser. (For the discharge of hydrogen ions an expression of this kind is obtained, the factor before the logarithm being  $2RT/F$ ; but the reasons for the factor 2 given in Gurney's theory will not apply to the transfer to a heavy molecule.) The fact that the experimental data are in reasonable agreement with this expression is an argument in favour of the direct reduction.

It has been suggested that the molecules which are reduced by a direct electron transfer are those which give rise to *reversible* oxidation potentials. But it is not necessary that a reversible potential should be established in every such case. The condition of reversibility is that there shall be a single potential at which electron transfers can take place from the electrode to the substance and from its reduction product to the electrode at the same and not inappreciable rate. The condition of transfer of electrons from the electrode to a molecule in solution is approximately stated as  $\phi + V < I_R$ , where  $\phi$  is the thermionic work function of the metal,  $V$  the potential difference, and  $I_R$  the electron affinity of the substance (taking account of any solvation and adsorption energies). The condition for the reverse process is  $I_O < \phi + V$ , where  $I_O$  is the ionisation potential of the oxidised form of the substance. In practice, if the two processes are to occur at the same potential it is necessary that  $I_O$  should be of nearly the same magnitude as  $I_R$ , i.e. the energy required to remove electrons from the oxidised form should be about the same as the electron affinity of the reduced form of the substance. Now, if the primary product of the reduction undergoes irreversible changes, this condition will not be satisfied and reduction may occur by direct electron addition without giving rise to a reversible potential.

It is not unreasonable to suppose that substances like nitrobenzene may have an electron affinity which enables them to act as electron acceptors. The nitrogen atom in nitrobenzene has an incomplete shell of electrons, and the process of reduction might occur by the gain of two

<sup>16</sup> Cf. Butler and Armstrong, *J. Chem. Soc.*, 1934, 743.

electrons, giving the ion  $\text{C}_6\text{H}_5\text{NO}_2^-$ , which by an irreversible reaction with hydrogen ions gives nitrosobenzene, the first product of the reduction, *viz.*:

A similar process can then occur again, but in this case it is believed to be reversible:

The reduction of the hydroxylamine to aniline apparently requires a more negative potential and may be a reduction by atomic hydrogen. It is interesting to observe that Conant<sup>17</sup> has suggested a similar mechanism for the reduction of hydroxylamine by ionic reducing agents.

We conclude that in these cases it is not improbable that the reduction is effected by the direct transfer of electrons from the electrode to the depolariser, but we cannot exclude definitely the possibility of reaction with adsorbed hydrogen which might be formed below the normal hydrogen overvoltage. A definite decision on this point must await the discovery of the conditions of formation and properties of adsorbed hydrogen on high overvoltage metals.

### Summary.

1. The possible modes of electrolytic reduction are reviewed and their distinguishing characteristics discussed.

2. Examples are given of various types. Acetone, sodium formate and pyridine at lead electrodes cause no significant displacement of the hydrogen overvoltage curve over the whole range, and are reduced by free atomic hydrogen. Nitrobenzene and benzaldehyde are reduced at mercury at more positive potentials than those at which hydrogen is liberated in their absence. With larger currents a transition occurs to near the hydrogen overvoltage. The time-potential curves show no sign of consecutive processes, and obey the relation  $(i - i_0)t = \alpha$ , which is characteristic of many cases in which the transition is due to the slow diffusion of the depolariser to the electrode. It is concluded that it is not improbable that these reductions are effected by direct transfer of electrons from the electrode, although reduction by adsorbed hydrogen, liberated below the normal overvoltage, cannot be definitely excluded. The adsorption of the substance on the electrode, which may displace the hydrogen overvoltage in the negative direction is illustrated by pyridine at platinum.

We thank Messrs. Imperial Chemical Industries for their grant.

# THE KINETICS OF THE NITRITE-IODINE REACTION.

BY GEORGE GEOFFREY DURRANT, ROBERT OWEN GRIFFITH AND  
ANDREW McKEOWN.

*Received 23rd March, 1936.*

Of the many thermal reactions of halogens in liquid solution, only a few are known in which it is presumed that halogen atoms play an essential rôle. Such are the reversible formation and decomposition of ethylene iodide in  $\text{CCl}_4$  solution,<sup>1</sup> and the reactions in aqueous solution between oxalates and iodine.<sup>2,3,4</sup> For various reasons we thought it likely that the reactions between nitrites and iodine in aqueous solution might also involve the intermediacy of iodine atoms. The thermal reaction between  $\text{KNO}_2$  and iodine has previously been studied by Berthoud and Berger<sup>5</sup> in connection with their study of the photochemical process, but only a few observations were made and the data obtained were insufficient to establish the mechanism. We have therefore re-investigated this thermal reaction—using both  $\text{KNO}_2$  and  $\text{NaNO}_2$  as reactants—under a wider range of experimental conditions, and have evolved a mechanism which accounts quantitatively for our results. This mechanism, which introduces iodine atoms or combinations of iodine atoms with iodide ions ( $\text{I}_2^-$  ions), is further supported by the results of experiments in which nitrite and oxalate react simultaneously with iodine. It also links up quantitatively the rate of the nitrite-iodine reaction with the rate of decomposition of  $\text{HNO}_2$  in aqueous solution, exhaustively investigated by Abel and his collaborators.<sup>6</sup>

## Experimental.

Kinetic measurements have been carried out at 40°, 50° and 60° with  $\text{NaNO}_2$  (and  $\text{KNO}_2$ ) and  $\text{I}_2$  as reactants. The reaction could only be studied over a limited range of  $p_{\text{H}}$ , since with too alkaline solutions appreciable loss of iodine by iodate formation occurs, and with solutions too acid complications are caused by the decomposition of free nitrous acid. The actual range of  $p_{\text{H}}$  over which it is permissible to neglect these disturbing processes depends not only on the temperature and the concentrations of reactants, but very markedly also on the concentration of free iodide; roughly, however, a suitable range of  $p_{\text{H}}$  for the isolation of the reaction between  $\text{NO}_2^-$  and  $\text{I}_2$  is given by the use of phosphate buffers, as already employed by Berthoud and Berger.<sup>5</sup> These authors have shown that the reaction rate under their experimental conditions is independent of  $p_{\text{H}}$ , at least over the range covered by a variation of  $[\text{HPO}_4^{--}]/[\text{H}_2\text{PO}_4^-]$  from 0.33 to 3. We, too, have found that for each set of experimental

<sup>6</sup> Abel *et al.*, *Z. physikal. Chem.*, A, 1928, **132**, 55; 1928, **134**, 279; 1928, **136**, 135, 419, 430; 1930, **148**, 337.

conditions (concentrations of reactants and of iodide) there is a more or less limited range of  $p_H$  within which the process measured is exclusively  $\text{NO}_2^- + \text{I}_2 + \text{H}_2\text{O} \rightarrow \text{NO}_3^- + 2\text{H}^+ + 2\text{I}^-$ , and whose velocity is independent of  $[\text{H}^+]$ . In most of our experiments phosphate buffers were employed; in addition, a few measurements have been effected in  $\text{NaHCO}_3$  solutions saturated with  $\text{CO}_2$  and in acetate buffers. The reaction rate was found to be dependent also on ionic environment; hence, in order to make legitimate comparisons the ionic strength ( $\mu$ ) in various series was kept approximately constant by addition of  $\text{NaClO}_4$ ,  $\text{NaNO}_3$  or  $\text{KNO}_3$ .

All the chemicals used were of A.R. quality. Reaction mixtures of high iodide content were contained in glass-stoppered flasks; samples withdrawn from time to time were run into excess of sodium arsenite solution and their iodine contents obtained by back-titration with standard iodine solution. This procedure is, however, not accurate enough when the iodide content is low (less than 0.03  $M$ ), owing to progressive loss of iodine by volatilisation; under these circumstances, a number of 20 c.c. samples were sealed in thin glass tubes (of about 30 c.c. capacity) at room temperature, and these were simultaneously immersed in the thermostat at 50° or 60°. From time to time a tube was withdrawn, rapidly cooled, then broken and the iodine estimated as before. In all cases light was rigidly excluded from the reacting system.

In formal agreement with the results of Berthoud and Berger, the reaction was found to be unimolecular with respect to iodine, but not of simple order with respect either to nitrite or to iodide (which retards the reaction). The order with respect to nitrite ( $n_{\text{NO}_2^-}$ ) lies between the limits of 1 and 2, approaching the lower limit when  $[\text{I}^-]$  is very small compared with  $[\text{NO}_2^-]$  and the upper limit when  $[\text{I}^-]$  is large. The order with respect to iodide ( $n_{\text{I}^-}$ ) is similarly dependent not only on the concentration of iodide, but also on that of nitrite. For a given concentration of nitrite  $n_{\text{I}^-}$  varies from between 0 and -1 at low  $[\text{I}^-]$  to a limit of -3 at high  $[\text{I}^-]$ . If we provisionally define the rate of reaction by the equation

$$-\frac{d[\Sigma\text{I}_2]}{dt} = \frac{k'[\text{NO}_2^-][\Sigma\text{I}_2]}{K_2 + [\text{I}^-]} \quad (1)$$

where  $[\Sigma\text{I}_2]$  = concentration of total titratable iodine,  $[\text{I}^-]$  = concentration of free iodide, and  $K_2 = \frac{[\text{I}^-][\text{I}_2]}{[\text{I}_2^-]}$  is the equilibrium constant of triiodide formation, the above statements may be reworded in the sense that  $k'$  is constant at low  $[\text{I}^-]$  and high  $[\text{NO}_2^-]$ , but decreases progressively as  $[\text{I}^-]$  is increased, finally becoming proportional to  $[\text{NO}_2^-]/[\text{I}^-]^2$ . Search for a kinetic expression to fit these findings led to the following empirical expression:

$$-\frac{d[\Sigma\text{I}_2]}{dt} = \frac{k[\text{NO}_2^-][\Sigma\text{I}_2]}{\{K_2 + [\text{I}^-]\} \left\{ A \frac{[\text{I}^-]^2}{[\text{NO}_2^-]} + 1 \right\}} \quad (2)$$

or 
$$k' = \frac{k}{A \frac{[\text{I}^-]^2}{[\text{NO}_2^-]} + 1} \quad (3)$$

where  $k$  and  $A$  are constants (at constant temperature) independent of  $[\text{NO}_2^-]$  and of  $[\text{I}^-]$ .

Equations (2) and (3) are found to be in excellent agreement with our kinetic data over a wide range of variation of  $[\text{NO}_2^-]$  and  $[\text{I}^-]$ , so long as the total ionic strength of the various reaction mixtures is maintained constant. The value of  $k'$  at constant  $[\text{NO}_2^-]$  and constant  $[\text{I}^-]$  is, however, sensitive to change in  $\mu$ , decreasing progressively as  $\mu$  is increased. Most of our experiments have been carried out at  $\mu \approx 0.7$  and  $\mu \approx 2.7$ . In the former event the ionic strength is made up of contributions from

$\text{NaNO}_3$ ,  $\text{KI}$ ,  $\text{Na}_2\text{HPO}_4$  and  $\text{KH}_2\text{PO}_4$ . For  $\mu \approx 2.7$ , reaction mixtures are also  $2M$  with respect to  $\text{NaNO}_3$ . Kinetic measurements with intermediate concentrations of  $\text{NaNO}_3$  showed that, so far as this salt is concerned, a simple relation holds over the whole range of  $[\text{NaNO}_3]$  from  $[\text{NaNO}_3] = 0$  to  $[\text{NaNO}_3] = 2.0$  between  $k'$  and  $\mu$ , *viz.*,

$$\log k'_{\mu_1} - \log k'_{\mu_2} = 0.153 (\mu_1 - \mu_2) \quad (4)$$

This same dependence of  $k'$  on  $\mu$  obtains at very different values of  $[\text{I}^-]^2/[\text{NO}_2^-]$ , from which it follows that it is the constant  $k$ , and not  $A$ , which is sensitive to  $\mu$ .

We have used equation (4) to correct the velocity coefficients  $k'$  obtained in the series  $\mu \approx 0.7$  and  $\mu \approx 2.7$  to the values  $k'_{\text{corr.}}$  they should have at  $\mu = 0.7$  and  $2.7$  respectively. This procedure is not free from criticism, since equation (4) only represents the neutral salt effect of  $\text{NaNO}_3$  upon  $k'$ , whereas the individual  $k'$ 's in each series should really be corrected not for varying  $\text{NaNO}_3$ , but for the neutral salt effects of  $\text{NaNO}_3$ ,  $\text{KI}$ ,  $\text{Na}_2\text{HPO}_4$ , and  $\text{KH}_2\text{PO}_4$  which may well be different from that of  $\text{NaNO}_3$ . The corrections applied, however, are in most cases only a few per cent. in the two series, so that the values of  $k'_{\text{corr.}}$  cannot be seriously in error on this account.

Before tabulating our experimental results, it is first necessary to discuss in more detail the conditions of acidity under which the reaction is not interfered with by side reactions. With solutions too alkaline, especially in the presence of low  $[\text{I}^-]$ , loss of iodine by iodate formation may ensue in presence or absence of nitrite. Blank experiments were made in absence of nitrite to determine at  $50^\circ$  and  $60^\circ$  and at various concentrations of iodide the lower limit of  $[\text{H}^+]$  at which this disturbing effect may safely be ignored. On the other hand, the reaction mechanism is indubitably changed if an upper limit of  $[\text{H}^+]$  be exceeded. This is primarily due to the decomposition of free nitrous acid according to

This has the effect that with high iodide concentrations the liberated  $\text{NO}_2$  reacts with iodide to give iodine (and  $\text{NO}$  is evolved), so that  $\text{I}_2$  is formed in systems not initially containing iodine, and hence a spuriously low rate for disappearance of iodine would be obtained. At low iodide concentrations, however, this effect may be negligible, but on the other hand the  $\text{NO}$  liberated reacts with iodine to give a spuriously high rate of disappearance of  $\text{I}_2$ . We have thus been forced to work between rather narrow limits of  $p_{\text{H}}$  which are about  $p_{\text{H}} = 6$  for low concentrations of iodide and  $p_{\text{H}} = 7$  for high concentrations of  $\text{I}^-$ . In all cases where any doubt might exist, the  $[\text{H}^+]$  was varied over at least a two-fold range to test for the absence of the above-mentioned side reactions. It should further be noticed that the presence of  $\text{NaNO}_3$ ,  $\text{NaClO}_4$  and other neutral salts causes considerable increase in the acidity of phosphate buffers. For example, addition of  $2.0 M$   $\text{NaNO}_3$  to a phosphate buffer in which  $[\text{Na}_2\text{HPO}_4]/[\text{KH}_2\text{PO}_4] = 0.1/0.1$  or  $0.15/0.03$  causes a fall in  $p_{\text{H}}$  of about  $0.6$  units. Hence, in the presence of appreciable quantities of one of these neutral salts the phosphate ratio  $[\text{Na}_2\text{HPO}_4]/[\text{KH}_2\text{PO}_4]$  cannot safely be reduced to as small a value as in absence of the salt.

In Table I. are given the results of kinetic experiments at  $50^\circ$  and  $60^\circ$  with  $\text{NaNO}_3$  and  $\text{I}_2$  as reactants in the presence of phosphate buffers. Tables I.(a) and (c) refer to an ionic strength of  $0.7$  (no added  $\text{NaNO}_3$ ), and Tables I.(b) and (d) to  $\mu = 2.7$  (*i.e.* with  $2.0 M$   $\text{NaNO}_3$  added). The initial iodine content was  $0.0027M$  or  $0.001M$  in most cases. The tables give the mean values of  $k'$  as defined by equation (1) and of  $k'_{\text{corr.}}$ , the values of  $k'$  corrected to  $\mu = 0.7$  or  $2.7$  by means of equation (4) as already explained. In evaluating  $k'$  we have employed for  $K$ , the values  $0.00225$  and  $0.0026$  at  $50^\circ$  and  $60^\circ$  respectively; as shown by the work of Kiss and

Urmánczy,<sup>7</sup> these may be taken as practically independent of  $\mu$  over the range of  $[\text{NaNO}_2]$  studied. Each of the five or six values of  $k'$  given by each experiment was obtained from equation (1) written in the form

$$k' = \frac{k_{\text{uni}}(K_2 + [\text{I}^-]_{\text{m}})}{[\text{NO}_2^-]_{\text{m}}}$$

where  $k_{\text{uni}}$  is the unimolecular velocity coefficient (time in minutes) with respect to iodine, and  $[\text{I}^-]_{\text{m}}$  and  $[\text{NO}_2^-]_{\text{m}}$  are mean values of  $[\text{I}^-]$  and  $[\text{NO}_2^-]$  over the relevant time interval. Since, under our experimental conditions, the coefficient  $k'$  is sensibly constant in each experiment, we give only the average value of  $k'$  in each experiment together with the average value of  $[\text{I}^-]_{\text{m}}/[\text{NO}_2^-]_{\text{m}}$ . Values of  $[\text{I}^-]$ , the concentration of free iodide during an experiment, have been evaluated from the initial concentrations of potassium iodide ( $c$  or  $[\text{KI}]_0$ ), and of iodine ( $a$ ) and the extents of reaction ( $x$ ) by means of the equation

$$[\text{I}^-] = \frac{1}{2}((c - a - K_2 + 3x) + \sqrt{(c - a - K_2 + 3x)^2 + 4K_2(c + 2x)}).$$

For each of these four series of experiments a plot of the reciprocal of  $k'_{\text{corr.}}$  against  $[\text{I}^-]^2/[\text{NO}_2^-]$  is found to give a straight line. This is illustrated for one of the series, that of Table I.(d), in Fig. 1. In the plot are also included data from additional experiments, which for brevity have been omitted from Table I.(d). The linearity of the plots of  $1/k'$  against  $[\text{I}^-]^2/[\text{NO}_2^-]$  shows that equation (3) holds (at constant ionic strength) over the whole range of variation of  $[\text{I}^-]$ ,  $[\text{NO}_2^-]$  and  $[\text{H}^+]$  covered by Table I. From the plots, or by applying the method of least squares, the

\* [NaNO<sub>3</sub>] = 1.44.† [NaNO<sub>3</sub>] = 1.20.

constants  $k$  and  $A$  of equation (3) may be evaluated. The results are shown in Table II., which also includes the result of an experiment at 40° with a low concentration of KI, from which  $k$  (but not  $A$ ) is directly obtained.

TABLE II.

Temp.	$\mu$ .	$A$ .	$k \cdot 10^5$ .	$k/K_1 = k_1$ .
40	2.7	—	2.94	0.0159
50	0.7	153.5	28.4	0.126
50	2.7	160.7	13.8	0.0612
60	0.7	145.7	115.4	0.444
60	2.7	140.2	56.6	0.2175

From these figures we may infer that  $A$  is independent of  $\mu$  and put  $A = 157$  at 50° and  $A = 143$  at 60°. Further, it is seen that at each temperature  $k$  is approximately halved by increasing the ionic strength by 2 units. This result confirms the use of equation (4) for correcting velocity coefficients for changes in  $\mu$ . The temperature coefficient of  $k$  between 50° and 60° is found to be 4.07 at  $\mu = 0.7$  and 4.11 at  $\mu = 2.7$ , or an average of 4.09.

## 1004 THE KINETICS OF THE NITRITE-IODINE REACTION

That  $\text{NaNO}_3$ , a resultant of the reaction, exerts none other than an environmental effect on the rate is shown by the experiments of Table III., in which added  $\text{NaNO}_3$  is replaced by  $\text{NaClO}_4$ .

TABLE III.

$$[\text{NaNO}_3]_0 = 0.1807; [\text{NaClO}_4] = 2.04; \mu \approx 2.7.$$

Temp.	$\frac{[\text{Na}_2\text{HPO}_4]}{[\text{NaH}_2\text{PO}_4]}$	$[\text{KI}]_0$	$\frac{\{[\text{I}^-]_m\}}{[\text{NO}_2^-]_m} \times 10^3$ av.	$k' \times 10^3$	$k'_{\text{corr.}} \times 10^3$
50°	0.12/0.12	0.002	0.04	13.9	13.9
60°	0.155/0.015	0.06	18.6	14.7	15.0
60°	0.12/0.12	0.002	0.04	58.3	58.3

Comparison of the values of  $k'$  of this table with those of Tables I.(b) and (d) shows that the effects of  $\text{NaNO}_3$  and  $\text{NaClO}_4$  on the rate are practically identical.

FIG. 1.—● = Phosphate buffers + = Bicarbonate buffers.

We have also carried out a few kinetic measurements at 60° with  $\text{KNO}_3$  as the reactant and  $\text{KNO}_2$  added to make  $\mu = 1.34$ . The same mechanism applies as heretofore, as shown by the results of Table IV.

The data of the last three experiments of this table are calculated from the experiments of Berthoud and Berger<sup>8</sup> under practically the same conditions of ionic strength and acidity; as is seen, they fall into line reasonably with our own results. The plot of  $1/k'$  against  $[\text{I}^-]^2/[\text{NO}_2^-]$  for these experiments gives  $A = 176$ ,  $k = 107.3 \times 10^{-5}$  and  $k_1 = 0.438$ . The constants  $A$  and  $k_1$  are both about 24 per cent. higher than those calculated (see Table II.) for  $\text{NaNO}_3 + \text{NaNO}_2$  at  $\mu = 1.34$ .

TABLE IV.—TEMP. = 60°;  $[\text{Na}_2\text{HPO}_4] = [\text{KH}_2\text{PO}_4] = 0.066$ ;  
 $\mu = 1.34$ ;  $K_2 = 0.00245$ .

$[\text{KNO}_2]_0$	$[\text{KNO}_2]$	$[\text{KI}]_0$	$\frac{[\text{I}^-]_m^2}{[\text{NO}_2^-]_m} \times 10^3$ Av.	$k' \times 10^5$
0.96	0.091	0.025	0.74	93.6
0.96	0.066	0.05	2.76	72.5
0.48	0.556	0.04	3.44	67.3
0.48	0.55	0.05	5.27	56.1
0.96	0.041	0.075	6.11	51.9
0.48	0.536	0.06	7.58	46.6

1.00	—	0.075	5.9	53.8
1.00	—	0.1125	12.9	32.5

Finally, in Table V. are given some of the results of kinetic measurements in solutions of high acidity, such that appreciable amounts of free nitrous acid are present. Clearly the mechanism which applies to the experiments of Tables I.-IV. no longer suffices.

TABLE V TEMP. 60°,  $[\text{NaNO}_2]_0 = 2.04$ .

\*  $[\text{NaClO}_4] = 2.04$  replacing  $\text{NaNO}_3$ .

The first experiment in Table V. refers to normal conditions, the remainder to solutions of high acidity. It is seen that in these cases (*i.e.* with low concentrations of  $\text{I}^-$ ), the rate of disappearance of  $\text{I}_2$  is greater than the normal, and that the discrepancy increases with increasing acidity, or increasing  $[\text{NO}_2^-]$ , or diminishing  $[\text{I}^-]$ . We do not propose to discuss in any detail the mechanism of the reaction under these conditions; further work will be necessary for its elucidation. It appears likely, however, that the chief processes concerned may be represented as

and

that probably all four reactions are fast ones, that with low values of  $[\text{I}^-]$  the rate of the reaction between  $\text{NO}$  and  $\text{I}_2$  is faster than its reversal, and that the rate of disappearance of  $\text{I}_2$  is essentially governed by the difference between these two rates.

## Reaction Mechanism.

Two main types of reaction mechanism can be formulated to give a satisfactory interpretation of our experimental results. These are:—

## Mechanism I.

## Mechanism II.

In each of these,  $\text{NO}_2$  appears as an intermediate, but Mechanism I involves atomic iodine, whereas Mechanism II. postulates a complex ( $\text{NO}_2\text{I}_2^-$ ) between the  $\text{NO}_2^-$  ion and  $\text{I}_2$ . In either case, the net rate of disappearance of iodine equals the rate of formation of nitrate, *viz.*,  $k_5[\text{NO}_2]^2$ . It should be noted that the reaction between  $\text{NO}_2$  and  $\text{H}_2\text{O}$  (velocity coefficient  $k_5$ ) is also reversible, but under our experimental conditions of low acidity this reversal may be neglected.

Confining attention for the moment to Mechanism I., the usual assumption of stationary state conditions for the intermediates—iodine atoms and  $\text{NO}_2$ —leads to the equation

$$k_1k_3[\text{NO}_2^-]^2[\text{I}_2] = k_2k_4[\text{NO}_2]^2[\text{I}^-]^2 + k_2k_5[\text{NO}_2]^3[\text{I}^-] + k_3k_5[\text{NO}_2^-][\text{NO}_2]^2.$$

In this we now neglect the second term on the right-hand side compared with the first and the third. This is equivalent to assuming that the rate of reaction 3 is fast compared with that of 2, and the rate of 4 fast compared with that of 5, *i.e.*, that the equilibrium  $\text{NO}_2^- + \text{I} \rightleftharpoons \text{NO}_2 + \text{I}^-$  is effectively maintained in all reacting systems. It follows that the net rate of reaction is given by

$$-\frac{d[\text{I}_2]}{dt} = k_5[\text{NO}_2]^2 = \frac{k_1[\text{NO}_2^-][\text{I}_2]}{\frac{k_2k_4}{k_3k_5} \frac{[\text{I}^-]^2}{[\text{NO}_2^-]} + 1} \quad (5)$$

$$\text{or} \quad -\frac{d[\text{I}_2]}{dt} = \frac{k_1K_3[\text{NO}_2^-][\text{I}_2]}{\{K_3 + [\text{I}^-]\} \left\{ \frac{k_2k_4}{k_3k_5} \frac{[\text{I}^-]^2}{[\text{NO}_2^-]} + 1 \right\}} \quad (5a)$$

in formal agreement with the empirical equation (2).

Mechanism II., with the corresponding assumptions with regard to the relative rates of the part-processes, leads to an equation identical with (5a), as does also an alternative form of Mechanism II., *viz.*,

We have, however, definite evidence (*vide infra*) in support of the view that iodine atoms participate in the reaction, and therefore we need not discuss Mechanism II. or its variants further.

Reverting to Mechanism I., it may be noted that addition to it of the

rapidly maintained equilibrium  $\text{I} + \text{I}^- \rightleftharpoons \text{I}_2^-$  still leads to an equation formally identical with (5a), and, in fact the mechanism Ia

which is a simple variant of Mechanism I., yields equation (5a) with the constants  $k'_1$ ,  $k'_2$ ,  $k'_3$  and  $k'_4$  substituted for  $k_1$ ,  $k_2$ ,  $k_3$  and  $k_4$  respectively. According to Griffith, McKeown and Winn,<sup>6</sup> the equilibrium constant

$K_4 = \frac{[\text{I}][\text{I}^-]}{[\text{I}_2^-]}$  is at most  $10^{-4}$ , and hence, even at the lowest concentrations of iodide here employed, the concentration of  $\text{I}_2^-$  exceeds that of I atoms. Mechanism Ia may therefore be somewhat more likely than Mechanism I., but as there appears to be no means of distinguishing between them, we may confine our further discussion to Mechanism I. itself.

Identifying  $k_1K_4$  and  $\frac{k_2k_4}{k_3k_5}$  of equation (5a) with the constants  $k$  and  $A$  respectively of equation (2), we obtain for the ratio  $\frac{k_2k_4}{k_3k_5}$  the values 157 at  $50^\circ$  and 143 at  $60^\circ$ . The values of  $k_1$  under the various conditions studied are given in the last column of Table II. These values refer to the reaction in media containing sodium salts. The values of  $k_1$  and  $\frac{k_2k_4}{k_3k_5}$  in presence of potassium salts at  $\mu = 1.34$  and  $60^\circ$  are 0.438 and 176 respectively. The temperature coefficients of  $k_1$  in the intervals  $40^\circ - 50^\circ$  and  $50^\circ - 60^\circ$  are 3.86 and 3.54 respectively, corresponding to a critical increment  $E_1$  of 27,000 cal. The ratio  $\frac{k_2k_4}{k_3k_5}$  definitely decreases with increasing temperature, but its dependence on temperature is relatively small. It corresponds to a "critical increment"  $E_A$  of — 2000 cal.

### Discussion.

Apart from the fact that Mechanism I. for the reaction between nitrite and iodine predicts the correct kinetic law, two independent tests of its validity are available. The first of these concerns the assumed intermediacy of  $\text{NO}_2$ , the second the rôle of iodine atoms in the reaction. We shall deal with these tests in order.

The mechanism of decomposition of nitrous acid in aqueous solution, which has been the subject of many investigations in the past, has been finally elucidated by the careful studies of Abel and his co-workers.<sup>6</sup> It has been found that the net reaction

is composite of the part-processes

<sup>6</sup> Griffith, McKeown and Winn, *Trans. Faraday Soc.*, 1933, **29**, 386.

of which ( $\beta$ ) is a rapidly maintained equilibrium, while ( $\gamma$ ) determines the measured rate of decomposition of the nitrous acid.\* Now reaction ( $\gamma$ ) has also been assumed to be the rate-determining step in our mechanism for the oxidation of nitrite by iodine, and accordingly it should be possible to correlate quantitatively our kinetic measurements of this reaction with those of Abel for the decomposition of nitrous acid. This may be done as follows.

Reaction ( $\alpha$ ) is found by Abel to follow the kinetic law

$$-\frac{d[\text{HNO}_2]}{dt} = k_\alpha \frac{[\text{HNO}_2]^4}{p_{\text{NO}}^2} \quad (6)$$

But from Abel's mechanism this rate is also given by

$$-\frac{d[\text{HNO}_2]}{dt} = -\frac{3}{2} \frac{d[\text{NO}_2]}{dt} = 3k_5[\text{NO}_2]^2 \quad (7)$$

where  $k_5$  is the velocity coefficient of process ( $\gamma$ ). Hence

$$k_5 = \frac{1}{3} k_\alpha \frac{[\text{HNO}_2]^4}{p_{\text{NO}}^2 [\text{NO}_2]^2} = \frac{1}{3} k_\alpha \frac{K_\beta^2}{D^2} \quad (8)$$

where  $K_\beta = \frac{[\text{HNO}_2]^2}{p_{\text{NO}} p_{\text{NO}_2}}$  is the equilibrium constant of process ( $\beta$ ) and  $D = \frac{[\text{NO}_2]}{p_{\text{NO}_2}}$  is the solubility coefficient of  $\text{NO}_2$  in water. On the other hand, the constants which we have evaluated from the nitrite-iodine reaction are the velocity constant  $k_1$  of the primary process

and the ratio  $\frac{k_2 k_4}{k_3 k_5} = A$  of the velocity constants of the other part-processes in Mechanism I. In terms of these we have

$$k_5 = \frac{k_1 (k_2 k_4)}{A (k_1 k_3)} \quad (9)$$

But the factor  $\frac{k_2 k_4}{k_1 k_3}$  is simply the equilibrium constant of the reaction

which is compounded of the  $k_1$ ,  $k_2$ ,  $k_3$ , and  $k_4$  reactions, or

$$\frac{k_2 k_4}{k_1 k_3} = \frac{K}{D^2} \quad (10)$$

where  $K$  is the equilibrium constant of the reaction

i.e.,

$$K = \frac{[\text{NO}_2^-]^2 [\text{I}_2]}{p_{\text{NO}_2}^2 [\text{I}^-]^2}$$

Combining (9) and (10), we obtain

$$k_5 = \frac{k_1}{A} \cdot \frac{K}{D^2} \quad (11)$$

\* Abel writes ( $\beta$ ) and ( $\gamma$ ) in terms of  $\text{N}_2\text{O}_4$ , instead of  $\text{NO}_2$ , a formal difference which naturally does not affect the argument.

and comparing (8) and (11) the following relation results between Abel's constant  $k_\alpha$  and our constants  $k_1$  and  $A$ :—

$$k_\alpha = \frac{3k_1}{A} \cdot \frac{K}{K_\beta^2} \quad (12)$$

It should thus be possible to evaluate Abel's  $k_\alpha$  at say 60° C. from our own velocity constants and the equilibrium constants  $K$  and  $K_\beta$  of the reactions

These equilibrium constants have been evaluated from the free energies of the participants at 25° and the heats of reaction, using the data from International Critical Tables. They are:

$$\begin{aligned} K(25^\circ) &= 6.9 \times 10^9; & K_\beta(25^\circ) &= 1.44 \times 10^2 \\ Q_p &= 33,800 \text{ cal.}; & Q_p &= 18,350 \text{ cal.} \\ K(60^\circ) &= 1.5 \times 10^7; & K_\beta(60^\circ) &= 5.54. \end{aligned}$$

Using equation (4) to correct our  $k_1$  of Table II. to zero ionic strength, we obtain  $k_1(\mu=0) = 0.568$  and  $A = 143$  at 60°. Hence  $k_\alpha$  at  $\mu=0$  and 60° is calculated from equation (12) to be 5825, whereas Abel's experimental value is 5130. In view of the inevitable uncertainties in the values of  $K$  and  $K_\beta$  the agreement is very satisfactory, and it must be regarded as strong evidence for the hypothesis that  $\text{NO}_2$  participates in the nitrite-iodine reaction in such a manner as to make the rate-determining process  $2\text{NO}_2 + \text{H}_2\text{O} \rightarrow \text{HNO}_2 + \text{HNO}_3$ .

As a further test of equation (12), the critical increment of  $k_\alpha$  may also be calculated from the temperature dependence of  $k_1$ ,  $A$ ,  $K$ , and  $K_\beta$ . We have

$$\begin{aligned} E_\alpha &= E_1 - E_A - Q_K + 2Q_{K_\beta} \quad (13) \\ &= 27,000 + 2000 - 33,800 + 36,700 \\ &= 31,900 \text{ cal.} \end{aligned}$$

This lies about 3000 cal. above Abel's value for  $E_\alpha$  of 28,600 cal. Probably this difference simply represents an accumulation of errors in the various terms involved.

Turning to the consideration of the rôle of iodine atoms in the nitrite-iodine reaction, it should at once be remarked that the deduction of equation (5) from Mechanism I. involves two major assumptions, one of which has hitherto not been explicitly stated. It has been assumed that the  $k_3$  and  $k_4$  reactions are always fast compared with the other processes in the mechanism, but it has also been implicitly assumed that these same reactions are fast compared with any such processes as  $\text{I}_2 \rightleftharpoons 2\text{I}$  or  $\text{I}_3^- + \text{I}^- \rightleftharpoons 2\text{I}_2^-$  (coupled with  $\text{I}_2 \rightleftharpoons \text{I}^- + \text{I}$ ) which, in the absence of nitrite, would maintain a thermal equilibrium concentration of iodine atoms  $[\text{I}]$ , in the system. In effect, we have postulated that the instantaneous concentration of iodine atoms is controlled solely by the

equilibrium  $\text{NO}_2^- + \text{I} \xrightleftharpoons[k_4]{k_3} \text{NO}_2 + \text{I}^-$ , and that the observed rate of reaction, viz.,  $k_5[\text{NO}_2]^{1/2}$ , represents the lack of balance between the  $k_1$  and  $k_3$  reactions. Without the progressive drain on the  $\text{NO}_2$  by the  $k_5$  reaction, the  $k_1$  and  $k_3$  reactions would also balance, and the  $\text{NO}_2 \rightleftharpoons \text{NO}_2^-$

couple would simply act as a catalyst for the production and disappearance of iodine atoms. Under these circumstances, however, the concentration of iodine atoms must assume its thermal equilibrium value  $[I]_e$ , and therefore

$$\frac{[NO_2]_e[I^-][I]_e}{[NO_2^-][I_2]} = \frac{k_1}{k_2} \quad (14)$$

and

$$\frac{[NO_2]_e[I^-]}{[NO_2^-][I]_e} = \frac{k_3}{k_4} \quad (15)$$

where  $[NO_2]_e$  is the stationary concentration of  $NO_2$  under these ideal conditions. The velocity constants  $k_1$ ,  $k_2$ ,  $k_3$  and  $k_4$  must therefore be such that

$$\frac{[I]_e^2}{[I_2]} = \frac{k_1 k_4}{k_2 k_3} \quad (16)$$

The actual occurrence of the  $k_5$  reaction upsets this balance and has the effect of reducing the concentrations of  $NO_2$  and I atoms below their equilibrium values. We now have

$$\frac{[NO_2][I^-]}{[NO_2^-][I]} = \frac{k_3}{k_4} \quad (17)$$

and

$$k_1[NO_2^-][I_2] - k_2[NO_2][I^-][I] = k_5[NO_2]^2 \quad (18)$$

from which, it may be noted, equation (5) directly follows. Combining equations (17) and (18) with (16), it also follows that the ratio ( $F$ ) of  $[I]$  to  $[I]_e$  is given by

$$F = \frac{[I]}{[I]_e} = \sqrt{\frac{A[I^-]^2/[NO_2^-]}{A[I^-]^2/[NO_2^-] + 1}} \quad (19)$$

where  $A = \frac{k_2 k_4}{k_3 k_5}$  as heretofore. Examination of equation (19) shows that  $[I]$  should approximate to  $[I]_e$  for high values of  $[I^-]^2/[NO_2^-]$ , that is for an observed slow rate of reaction between nitrite and iodine, whereas for low values of  $[I^-]^2/[NO_2^-]$ , that is, for a high rate of reaction, the concentration of iodine atoms should be maintained considerably less than its thermal equilibrium value.

Now we have previously demonstrated,<sup>3</sup> and the result has been confirmed by other workers,<sup>2, 4</sup> that the thermal reaction between iodine and an oxalate is composite of two simultaneous processes, the one unimolecular, the other semi-molecular with respect to iodine. The first of these is interpreted as a reaction between  $HC_2O_4^-$  ions and  $HIO$ , the other as a reaction between  $C_2O_4^{--}$  ions and iodine atoms. If iodine atoms participate also in the nitrite-iodine reaction as above described, it follows on the basis of the above analysis that in a reaction mixture containing nitrite, oxalate, and iodine, the iodine should be consumed at a rate less than that computed as the additive effect of the separate reactions of iodine with oxalate and with nitrite. We have carried out experiments to test this; the predicted decrease in the rate of consumption of iodine is confirmed, and furthermore the results may be quantitatively interpreted on the basis of equation (19).

Solutions of oxalates, in which the oxalate ion present is predominately  $C_2O_4^{--}$ , react with  $I_2$  according to the equation<sup>3</sup>

$$-\frac{d[\Sigma I_2]}{dt} = [C_2O_4^{--}] \left\{ \frac{\sqrt{[\Sigma I_2]}}{\sqrt{K_3} + [I^-]} + k_1'' \frac{[\Sigma I_2]}{[I^-]\{K_3 + [I^-]\}} \right\} \quad (20)$$

where the first term inside the brackets refers to the semi-molecular process and the second to the unimolecular process. Hence it follows that in solutions containing both nitrite and oxalate the rate of consumption of iodine should be given by

$$-\frac{d[\Sigma I_2]}{dt} = [C_2O_4^{--}] \left\{ k_1 F \frac{\sqrt{[\Sigma I_2]}}{\sqrt{K_3 + [I^-]}} + k_1'' \frac{[\Sigma I_2]}{[I^-] \{K_3 + [I^-]\}} \right\} + k' \frac{[NO_2^-][\Sigma I_2]}{K_3 + [I^-]} \quad (21)$$

where  $F$  is defined by equation (19). From separate experiments in absence of nitrite, carried out at  $50^\circ$  and  $\mu=0.95$ , we find  $k_1''=38.0 \times 10^{-8}$  and  $k_1=48.2 \times 10^{-6}$ . Using these values of  $k_1''$  and  $k_1$  and the pertinent values of  $k'$  for the nitrite-iodine reaction, we have employed equation (21) to calculate the rates of disappearance of iodine in solutions containing both oxalate and nitrite, and have compared these rates with those found experimentally. As equation (21) is non-integrable, we have used the method of finite differences, and have calculated values of  $\Delta[\Sigma I_2]_{tot.}$ , gram-molecules of  $I_2$  transformed per litre, in time intervals  $\Delta t$  from the equation

$$\Delta[\Sigma I_2]_{tot.} = \Delta t \left[ [C_2O_4^{--}] \left\{ k_1 F \frac{\sqrt{[\Sigma I_2]_m}}{\sqrt{K_3 + [I^-]_m}} + k_1'' \frac{[\Sigma I_2]_m}{[I^-]_m \{K_3 + [I^-]_m\}} \right\} + k' \frac{[NO_2^-][\Sigma I_2]_m}{K_3 + [I^-]_m} \right] \quad (21a)$$

I. II. III.

where  $[\Sigma I_2]_m$  and  $[I^-]_m$  are the mean values of the concentrations of titratable iodine and of iodide over the relevant time interval, and I, II, and III are the separate contributions of the three terms on the right-hand side of the equation to the total  $\Delta[\Sigma I_2]$ .

Table VI. reproduces the results of one such experiment and the calculations based thereon.

The last column in the upper half of the table gives the observed amounts of iodine disappeared, and the last two columns in the lower half give the calculated values:

(a) With the assumption that the oxalate-iodine and nitrite-iodine reactions are additive, that is, making  $F = 1$  in equation (21a);

(b) Using equation (21a) with the values of  $F$  given in the table and based on equation (19).

It will be seen that the values calculated by method (b) are in good agreement with the experimentally observed values, whereas method (a) gives values considerably too high. We have carried out five such test experiments in all. Space will not permit of reproducing the results of these in detail, but their main features may be summarised as follows. In them the value of  $F$  has been varied from 0.15 to 0.95. Calculation by method (a) yields consistently high values for  $\Delta[\Sigma I_2]_{tot.}$ , deviations up to 35 per cent. being obtained. Calculating by method (b), two of the experiments give values of  $\Delta[\Sigma I_2]_{tot.}$  (calc.) slightly higher than the observed values; in the remaining three experiments (of which the experiment of Table VI. is one) the reverse is true. In no case, however, is any single value of  $\Delta[\Sigma I_2]_{tot.}$  calculated by method (b) more than 5 per cent. different from the observed value. The results of these five

## 1012 THE KINETICS OF THE NITRITE-IODINE REACTION

TABLE VI.— $[\text{NaNO}_2] = 0.1807$ ;  $[\text{NaKC}_2\text{O}_4] = \frac{1}{2}$ ;  $[\text{Na}_2\text{HPO}_4] = 0.05$ ;  $[\text{KH}_2\text{PO}_4] = 0.1$ ;  $[\text{KI}]_0 = 0.01$ ;  $[\Sigma\text{I}]_0 = 0.002$  APPROX.; TEMP. =  $50^\circ$ ;  $\mu = 0.94$ .

82.63	5.03	2.42	18.62	3.652	2.607

experiments are thus entirely consistent with equation (19), and therefore with the theory that iodine atoms participate in the nitrite-iodine reaction.

Finally, it is to be noted that of the velocity constants,  $k_1$ ,  $k_2$ ,  $k_3$ ,  $k_4$  and  $k_5$  of our mechanism, only  $k_1$  is at present determinable. The others, or more precisely  $k_3$ ,  $k_5$  and the ratio  $k_3/k_4$ , could be calculated from existing data if a knowledge of the solubility coefficients of  $\text{NO}_2$  and of monatomic iodine in water were available. As this is not the case, we may for the present refrain from speculating on these matters. It is hoped, however, that the *photochemical* reaction between nitrite and iodine, which we are now re-investigating, may shed further light on the reaction mechanism.

### Summary.

The kinetics of the nitrite-iodine reaction have been investigated in phosphate buffers at temperatures of  $40^\circ$ ,  $50^\circ$  and  $60^\circ$ . The reaction rate is given by

$$-\frac{d[\Sigma\text{I}_2]}{dt} = k \frac{[\text{NO}_2^-][\Sigma\text{I}_2]}{\{K_3 + [\text{I}^-]\left\{A \frac{[\text{I}^-]^2}{[\text{NO}_2^-]} + 1\right\}}}$$

where  $k$  and  $A$  are constants and  $K_3$  is the tri-iodide equilibrium constant.  $k$  and  $A$  have been evaluated at different temperatures and for different neutral salt environments. This kinetic equation has been interpreted in terms of a reaction mechanism involving  $\text{NO}_2$  and iodine atoms as intermediaries. The presumed rôle of  $\text{NO}_2$  is substantiated by comparison of

our kinetic data with those of Abel and co-workers for the decomposition of free nitrous acid, while independent confirmation of the rôle of iodine atoms in the reaction has been obtained by use of the iodine-oxalate reaction as an "indicator reaction" for iodine atoms.

## MEAN VALUES FOR THE DIPOLE MOMENTS OF THE HARMONIC AND ANHARMONIC OSCILLATOR IN QUANTUM MECHANICS.

BY R. P. BELL AND E. A. GUGGENHEIM.

*Received 25th March, 1936.*

In a previous paper,<sup>1</sup> one of the authors has calculated the mean dipole moment of a classical harmonic oscillator, and shown that for polarisable ions the mean moment is a function of the amplitude. This result was then applied to calculate the difference in the mean dipole moments of isotopic molecules arising from the difference in the amplitudes of the zero point vibrations. Such a procedure is open to criticism, since zero point energy is essentially a quantum mechanical phenomenon, and cannot be legitimately treated as a classical vibration. In particular, the eigenfunction of the lowest state of a harmonic oscillator shows that the configuration of maximum probability corresponds to the position of equilibrium, while in a classical oscillator the particle is most likely to be found at the extremes of its motion.<sup>2</sup> The present paper gives a quantum mechanical calculation of the mean values involved, and extends the treatment to higher vibrational states and (to a first approximation) to an anharmonic oscillator.

The variation of the instantaneous dipole moment with the inter-nuclear distance depends on the electronic distribution and cannot be represented accurately by any general theoretical or empirical equation. The electrical state of a diatomic molecule can, however, be represented at least approximately by a model consisting of polarisable ions. In the present paper we shall consider only the case in which only one of the ions is polarisable, corresponding to a diatomic molecule or group in which one of the atoms is hydrogen (or deuterium). The instantaneous dipole moment is then given by

$$\mu = e(a + x) - \frac{\alpha e}{(a + x)^2} \cdot \cdot \cdot \cdot (1)$$

<sup>1</sup> R. P. Bell, *Trans. Faraday Soc.*, 1935, **31**, 1345.

<sup>2</sup> The same criticism applies in principle to any quantitative treatment of zero point energy as a classical vibration, e.g. in dealing with the minimum distance of approach of isotopic molecules (cf. R. P. Bell and J. H. Wolfenden, *J. Chem. Soc.*, 1935, 823; A. R. Ubbelohde, *Trans. Faraday Soc.*, 1936, **32**, 525), though the results of the present paper show that the errors involved in a classical treatment will in most cases be small.

and the moment in the equilibrium position by

$$\mu_0 = ea - \frac{e\alpha}{a^2}, \quad (2)$$

where  $a$  is the equilibrium distance between ions of charges  $+e$  and  $-e$ ,  $x$  is the displacement from the equilibrium position, and  $\alpha$  the polarisability of one of the ions.

It is convenient to introduce a new variable  $\xi$  defined by  $x = b\xi$ , where  $b = (h/4\pi^2 m\nu)^{\frac{1}{2}}$  is the amplitude of a classical harmonic oscillation of energy  $\frac{1}{2}h\nu$ ,  $m$  being the reduced mass and  $\nu$  the frequency. The expression for  $\mu$  can then be expanded in powers of  $\xi$ , giving

$$\begin{aligned} \frac{\mu}{ea} &= \frac{a + b\xi}{a} - \frac{\alpha}{a(a + b\xi)^2} \\ &= \frac{\mu_0}{ea} + \xi \frac{b}{a} \left( 1 + \frac{2\alpha}{a^3} \right) - \xi^2 3 \frac{b^2}{a^2} \frac{\alpha}{a^3} + \xi^3 4 \frac{b^3}{a^3} \frac{\alpha}{a^3} - \xi^4 5 \frac{b^4}{a^4} \frac{\alpha}{a^3} + O(\xi^5). \end{aligned} \quad (3)$$

Since in practice  $b/a < 1/10$ , it is necessary to retain only the first few terms of the expansion. The mean value of  $\mu$  is then obtained by inserting the mean values of  $\xi$ ,  $\xi^2$ , etc., in equation (3). Any empirical or theoretical expression for  $\mu$  which is more accurate than equation (1) can be treated in the same way by expanding in powers of  $\xi$ .

The mean value of  $\xi^r$  in the  $n$ th vibrational state is given by

$$\bar{\xi^r} = \int_{-\infty}^{+\infty} \psi_n^2 \xi^r dx = b \int_{-\infty}^{+\infty} \psi_n^2 \xi^r d\xi, \quad (4)$$

where  $\psi_n$  is the normalised wave function.  $\psi_n$  has the well-known form

$$\psi_n = \left\{ \frac{1}{2^n n! b \pi^{\frac{1}{2}}} \right\}^{\frac{1}{2}} e^{-\xi^2/2} H_n(\xi) \quad (5)$$

where  $H_n(\xi)$  is the  $n$ th Hermitean polynomial. For present purposes these polynomials are most conveniently defined by means of the generating function

$$S(\xi, s) = e^{\xi^2 - (s - \xi)^2} = \sum_n \frac{H_n(\xi)}{n!} s^n. \quad (6)$$

The integrals in equation (4) are evaluated by taking a second generating function

$$T(\xi, t) = e^{\xi^2 - (t - \xi)^2} = \sum_k \frac{H_k(\xi)}{k!} t^k,$$

and considering the product

$$\begin{aligned} \int_{-\infty}^{+\infty} S T e^{-\xi^2} \xi^r d\xi &= e^{2st} \int_{-\infty}^{+\infty} e^{-(\xi - s - t)^2} \xi^r d\xi \\ &= e^{2st} \int_{-\infty}^{+\infty} e^{-\xi^2} (\xi + s + t)^2 d\xi = \sum_n \sum_k \frac{s^n t^k}{n! k!} \int_{-\infty}^{+\infty} H_n H_k e^{-\xi^2} \xi^r d\xi. \end{aligned} \quad (7)$$

The value of  $\int_{-\infty}^{+\infty} H_n H_k e^{-\xi^2} \xi^r d\xi$  is obtained by expanding  $e^{2st}$  and equating coefficients of  $s^n t^k$  in the last two expressions in equation (7). Only integrals with  $n = k$  are required in equation (4).

The following results are obtained

$$\overline{\xi_n^r} = 0 \quad \text{if } r \text{ is odd,} \quad (8)$$

$$\overline{\xi_n^3} = n + \frac{1}{2}, \quad \overline{\xi_n^4} = \frac{3}{2}(n^2 + n + \frac{1}{2}).$$

Inserting these values in equation (3)

$$\frac{\bar{\mu} - \mu_0}{ea} = -\frac{\alpha}{a^3} \left\{ 3(n + \frac{1}{2}) \frac{b^2}{a^2} + \frac{15}{2}(n^2 + n + \frac{1}{2}) \frac{b^4}{a^4} + O \left( \frac{b^6}{a^6} \right) \right\}. \quad (9)$$

For the particular case of a molecule in its lowest vibrational state (as is actually the case at ordinary temperatures)

$$\frac{\bar{\mu} - \mu_0}{ea} = -\frac{\alpha}{a^3} \left\{ \frac{3}{2} \frac{b^2}{a^2} + \frac{15}{4} \frac{b^4}{a^4} + O \left( \frac{b^6}{a^6} \right) \right\}. \quad (10)$$

Equation (9) can be used to estimate the change of  $\bar{\mu}$  at high temperatures due to an increase in the vibrational quantum number, and equation (10) to estimate the dependence of  $\bar{\mu}$  upon  $b$  and hence upon the mass of the atoms (isotope effect). In both cases the effect would be absent for a dipole consisting of non-polarisable ions ( $\alpha = 0$ ).

For a classical harmonic oscillator having the same energy,  $\xi$  is given by

$$\xi_n = \sqrt{2n+1} \sin 2\pi\nu t, \quad (11)$$

and the mean values of  $\xi^2$  and  $\xi^4$  become

$$\overline{\xi_n^2} = (2n+1) \overline{\sin^2 \theta} = n + \frac{1}{2}$$

$$\overline{\xi_n^4} = (2n+1)^2 \overline{\sin^4 \theta} = \frac{3}{2}(n^2 + n + \frac{1}{2}). \quad (12)$$

Comparison with equation (8) shows that the classical and quantum mechanical treatments give identical values for  $\overline{\xi_n^2}$ , but different values for  $\overline{\xi_n^4}$  (and for higher powers of  $\xi^2$ ); hence the classical treatment gives the value for  $\bar{\mu}$  correct to terms in  $b^2/a^2$ . As would be expected, the divergence between the two sets of results becomes relatively smaller as  $n$  increases.

For practical purposes the value of  $\overline{\mu^2}$  is much more important than that of  $\bar{\mu}$ : for instance, the experimental measurement of dipole moments always gives the root mean square moment and not the mean moment. From equation (3)

$$\begin{aligned} \frac{\mu^2}{e^2 a^2} &= \frac{(a + b\xi)^2}{a^2} - \frac{2\alpha}{a^3(a + b\xi)} + \frac{\alpha^2}{a^2(a + b\xi)^4} \\ &= \frac{\mu_0^2}{e^2 a^2} + \xi^2 \frac{b}{a} \left( 2 + \frac{2\alpha}{a^3} - \frac{4\alpha^2}{a^6} \right) + \xi^4 \frac{b^2}{a^2} \left( 1 - \frac{2\alpha}{a^3} + \frac{10\alpha^2}{a^6} \right) \\ &\quad + \xi^2 \frac{b^3}{a^3} \left( \frac{2\alpha}{a^3} - \frac{20\alpha^2}{a^6} \right) - \xi^4 \frac{b^4}{a^4} \left( \frac{2\alpha}{a^3} - \frac{35\alpha^2}{a^6} \right) + O(\xi^5). \end{aligned} \quad (13)$$

Inserting the mean values from equation (8),

$$\begin{aligned} \frac{\overline{\mu^2} - \mu_0^2}{e^2 a^2} &= (n + \frac{1}{2}) \frac{b^2}{a^2} \left( 1 - \frac{2\alpha}{a^3} + \frac{10\alpha^2}{a^6} \right) \\ &\quad - \frac{3}{2}(n^2 + n + \frac{1}{2}) \frac{b^4}{a^4} \left( \frac{2\alpha}{a^3} - \frac{35\alpha^2}{a^6} \right) + O \left( \frac{b^6}{a^6} \right). \end{aligned} \quad (14)$$

and for the lowest vibrational state,

$$\frac{\bar{\mu}^2 - \mu_0^2}{e^2 a^2} = \frac{1}{2} \frac{b^2}{a^2} \left( 1 - \frac{2\alpha}{a^3} + \frac{10\alpha^2}{a^6} \right) - \frac{3}{4} \frac{b^4}{a^4} \left( \frac{2\alpha}{a^3} - \frac{35\alpha^2}{a^6} \right) + O \left( \frac{b^6}{a^6} \right). \quad (15)$$

Equations (14) and (15) show that even for a dipole composed of non-polarisable ions the observed moment (unlike  $\bar{\mu}$ ) will depend upon the vibrational level and upon the mass of the particles. Further, the expression  $\left( 1 - \frac{2\alpha}{a^3} + \frac{10\alpha^2}{a^6} \right)$  (which is the only coefficient of importance in practice) is always positive, so that the observed moment will always increase with increasing vibrational quantum number, and will be greater for a hydrogen compound than for the corresponding deuterium compound. (The opposite conclusions are reached by considering  $\bar{\mu}$ : cf. equations (9) and (10).)

As an example we shall apply our formulæ to the HCl and DCl molecules, although they are not strictly applicable to this case. Our formulæ are derived for a molecule in which the vibrating particles are ions. If, on the other hand, the vibrational quantum number of the HCl molecule is steadily increased without altering the electronic quantum number, the molecule gradually dissociates into two neutral atoms, not into two ions. However, we believe that the inaccuracy of our model may be partly compensated by taking as the value of the polarisability of  $\text{Cl}^-$  not the true value but the value calculated from equation (2) and the experimental value<sup>3</sup> for  $\mu$ . For HCl we have then

$$a = 1.23 \times 10^{-8}, \quad b = 1.08 \times 10^{-9}, \quad (\bar{\mu}^2)^{\frac{1}{2}} = 1.03 \times 10^{-18} \text{ (at ordinary temperatures)}, \quad \alpha = 1.70 \times 10^{-24}.$$

$(\bar{\mu}^2)^{\frac{1}{2}}$  for DCl is found to be  $0.91 \times 10^{-18}$ , a difference which should be easily detected experimentally. (The only measurements with deuterium compounds so far reported deal with  $\text{D}_2\text{O}$  and  $\text{ND}_3$ , both of which are found to have a moment slightly *greater* than the corresponding hydrogen compounds. However, both these molecules are bent, and the effect is probably due to a change in the angle between the bonds.) It is similarly found that for HCl molecules in the first excited vibrational level ( $n = 1$ )  $(\bar{\mu}^2)^{\frac{1}{2}} = 1.62 \times 10^{-18}$ . There should thus be a considerable increase in the observed moment at sufficiently high temperatures, though it would hardly be observable at temperatures below about  $1000^\circ$ . Quite apart from the validity of any particular model, data for simple linear molecules such as HCl and DCl would give valuable information about the variation of electron distribution with internuclear distance.

The same treatment can easily be extended to obtain a first approximation for a slightly anharmonic oscillator. If the potential energy of the oscillator is given by

$$V = 2\pi^2 m \nu^2 x^2 - \beta x^3 \quad . \quad . \quad . \quad (16)$$

then the first order wave function for the  $n$ th vibrational state is

$$\psi'_n = \psi_n + \beta \sum_{k=0}^{\infty} \frac{\int_{-\infty}^{+\infty} \psi_n \psi_k x^3 dx}{W_n - W_k} \psi_k, \quad . \quad . \quad (17)$$

<sup>3</sup> Cf. Debye, *Polare Molekeln*, p. 73, Leipzig, 1929.

where  $\psi_n, W_n$  are the wave function and the energy when  $\beta = 0$ . Putting  $W_n = (n + \frac{1}{2})h\nu$ , and using equation (7) to evaluate the integrals, this gives

$$\psi'_n = \psi_n + \frac{\beta h^{\frac{1}{2}}}{8\pi^3 m^{\frac{3}{2}} \nu^{\frac{5}{2}}} \{3(n+1)^{\frac{3}{2}} \psi_{n+1} - 3n^{\frac{3}{2}} \psi_{n-1} + \frac{1}{4} \sqrt{(n+1)(n+2)(n+3)} \psi_{n+3} - \frac{1}{4} \sqrt{n(n-1)(n-2)} \psi_{n-3}\} \quad (18)$$

The mean values of  $\xi', \xi'',$  etc., are then calculated by inserting this wave function in equation (4), again using equation (7). The results of somewhat laborious calculations are as follows:—

$$\left. \begin{aligned} \bar{\xi}' &= \frac{3\beta h^{\frac{1}{2}}}{16\pi^3 m^{\frac{3}{2}} \nu^{\frac{5}{2}}} (2n+1) \\ \bar{\xi}'' &= (n + \frac{1}{2}) + \frac{\beta^2 h}{9216\pi^6 m^3 \nu^5} \{238n^4 + 404n^3 + 1415n^2 + 1231n + 339\} \\ \bar{\xi}''' &= \frac{\beta h^{\frac{1}{2}}}{32\pi^3 m^{\frac{3}{2}} \nu^{\frac{5}{2}}} \{30n^2 + 30n + 11\} \\ \bar{\xi}'''' &= \frac{1}{2}(n^2 + n + \frac{1}{2}) + \frac{\beta^2 h}{6144\pi^6 m^3 \nu^5} \{172n^5 + 430n^4 + 3462n^3 + 5432n^2 + 4030n + 1059\} \end{aligned} \right\} \quad (19)$$

The corresponding values of  $\bar{\mu}$  and  $\bar{\mu}^2$  are obtained by inserting these mean values in equations (3) and (13). Since for an actual molecule  $\beta$  is positive, the anharmonic terms increase the effects described above.

## A NOTE ON EVAPORATION FROM IRREGULAR SURFACES.

By H. W. MELVILLE.

*Received 27th April, 1936.*

In making use of the Herz-Knudsen effusion equation to determine the vapour pressure of a substance by sublimation in a vacuum two simplifying assumptions are made, (a) the condensation coefficient of molecules on the surface from which they are evaporating is unity, and (b) the effective area of the surface, if irregular, is equal to its projected geometrical area. It might be imagined, however, that if the surface from which evaporation is taking place is made extremely rough, then the rate of evaporation would be increased in proportion to the increase in surface area, much in the same way as the catalytic activity of a material is believed to be considerably increased by breaking up its surface by successive oxidations and reductions. In point of fact the increase in rate of evaporation on roughening a surface has been suggested as a means of finding the true area of the surface.<sup>1</sup>

<sup>1</sup> Cf. Rideal, *Surface Chemistry*, p. 177.

In the previous paper the above question is of importance, and therefore an attempt to estimate the magnitude of this unknown factor has been made in the following way.

As a first approximation matters will be simplified by considering only a vertical crack of unit length measured along the surface of the solid. The width of the crack is  $2a$ , the length of side 1 and the angle  $\theta$  as shown in Fig. 1. It will be assumed first of all that the condensation coefficient is unity, then any molecule evaporating from the elementary patch at P within the angle APB will escape while those evaporating within the angle BPC will condense on the other side of the crack. If the length of crack from F to C is only taken into account, the rate of evaporation, assuming the cosine law to

FIG. 1.

hold valid, will be given by the equation

$$W_1 = 2 \cdot 2^{-1} \cdot A \int_{2a \sin \theta}^{a' \sin \theta} \int_{\phi}^{\pi/2} \cos \phi \, d\phi \, dx$$

both sides of the crack being taken into consideration.  $A$  is a suitable proportionality constant. The contribution made by that part of the crack from  $A$  to  $E$  is likewise given by

$$W_2 = 2 \cdot 2^{-1} \cdot A \cdot \int_0^{2a \sin \theta} \int_{\phi'}^{\pi/2} \cos \phi' \, d\phi' \, dx$$

The total rate of evaporation is therefore

$$W = A \int_{2a \sin \theta}^{a' \sin \theta} (1 - \sin \phi) \, dx + \int_0^{2a \sin \theta} (1 + \sin \phi') \, dx$$

From the geometry of the problem

$$x \sin (\pi/2 - \phi) = 2a \sin (\theta + \phi)$$

$$\text{or} \quad \sin \phi = \frac{x - 2a \sin \theta}{(x^2 - 4ax \sin \theta + 4a^2)^{1/2}}$$

Therefore

$$\begin{aligned} W &= A \int_0^{2a \sin \theta} \left( 1 - \frac{x - 2a \sin \theta}{(x^2 - 4ax \sin \theta + 4a^2)^{1/2}} \right) dx \\ &= 2aA \end{aligned}$$

This means that no increase in vapour pressure occurs, no matter how irregular the nature of the surface provided all molecules which hit the solid condense.

**Condensation Coefficient less than Unity.**—Let the fraction of molecules which condense be  $\beta$ . The problem then is to consider the fate of molecules evaporating from one side, part escaping, part condensing and part being reflected. At each reflection a certain fraction escape and so contribute to the vapour pressure.

The total rate of evaporation from the surface of the crack is  $2aA \operatorname{cosec} \theta$ .

1. The amount which escapes is  $2\alpha A$  and therefore the amount which hits the opposite wall is  $2\alpha A(\operatorname{cosec} \theta - 1)$ , of these only  $\beta$  condense. The remainder  $(1 - \beta) 2\alpha A(\operatorname{cosec} \theta - 1)$  evaporate.

2. Of these a fraction  $\sin \theta$  escape, *i.e.*,  $\frac{(1 - \beta) 2\alpha A(\operatorname{cosec} \theta - 1) \sin \theta}{(1 - \sin \theta)}$  hits the opposite wall, *i.e.*,

$$(1 - \beta) 2\alpha A (\operatorname{cosec} \theta - 1) (1 - \sin \theta);$$

of these  $\beta$  condense. The remainder

$$(1 - \beta)^2 2\alpha A (\operatorname{cosec} \theta - 1) (1 - \sin \theta) \times \sin \theta$$

evaporate.

3. Of these a fraction  $\sin \theta$  escapes, *i.e.*,

$$\frac{(1 - \beta)^2 2\alpha A (\operatorname{cosec} \theta - 1) (1 - \sin \theta) \times \sin^2 \theta}{(1 - \sin \theta)}$$

of these a fraction  $(1 - \sin \theta)$  hits the opposite wall, *i.e.*,

$$(1 - \beta)^2 2\alpha A (\operatorname{cosec} \theta - 1) (1 - \sin \theta)^2 (\sin^2 \theta)$$

of these  $\beta$  condense. The remainder

$$(1 - \beta)^3 2\alpha A (\operatorname{cosec} \theta - 1) (1 - \sin \theta)^2 \sin^2 \theta$$

evaporate.

4. Of these a fraction  $\sin \theta$  escape, *i.e.*,

$$\frac{(1 - \beta)^3 2\alpha A (\operatorname{cosec} \theta - 1) (1 - \sin \theta)^2 \sin^3 \theta}{(1 - \sin \theta)}$$

For the  $n$ th evaporation

$$\frac{(1 - \beta)^{n-1} 2\alpha A (\operatorname{cosec} \theta - 1) (1 - \sin \theta)^{n-2} \sin^{n-1} \theta}{(1 - \sin \theta)}$$

escape.

$1 - \beta$ ,  $\sin \theta$  and  $(1 - \sin \theta)$  are all less than unity and hence the sum of the terms of the series converges to a finite magnitude. Its value is

$$2\alpha A \left\{ 1 + (1 - \beta) (\operatorname{cosec} \theta - 1) \sin \theta + \frac{(1 - \beta)^2 (\operatorname{cosec} \theta - 1) \sin^2 \theta (1 - \sin \theta)}{1 - (1 - \beta) \sin \theta (\operatorname{cosec} \theta - 1) (1 - \sin \theta)} \right\}$$

The factor within the bracket has been evaluated for a number of different values of  $\alpha$  and of  $\theta$  and the results are shown in Fig. 2. In the first place

it will be seen that the limits for  $\theta = 0$  and for  $\theta = 90$  are unity. Even with the small condensation coefficient of 0.1 and assuming random distribution of crack angles, the vapour pressure is only increased by a factor of 1.3 to 1.4. If, however, the cracks were

FIG. 2.

numerous and their angles had a tendency to be less than say  $5^\circ$ , then the vapour pressure, on this account, would be erroneous by the

comparatively small factor of two. For phosphorus there is some evidence that the condensation coefficient is not much less than unity at temperatures from  $-180^{\circ}$  to  $15^{\circ}$  C. The position of the deposit from the plate and also observations on the distribution of the red phosphorus opposite the filaments in the experiments described in the preceding paper show that the  $P_4$  molecule condenses nearly every time it collides with the surface provided this consists of red phosphorus. The conclusion is therefore that the above described effect does not modify the results given in the preceding paper.

### Summary.

An investigation has been made of the effect of cracks in a surface on the vapour pressure as determined by molecular distillation. It is shown that if the condensation coefficient is unity there is no increase in the rate of evaporation. If the condensation coefficient is not unity, the rate of evaporation is increased by a relatively small factor, *e.g.*, 1.3 for a condensation coefficient of 0.1.

The author is indebted to Dr. J. K. Roberts for critical discussions on this and on the preceding paper.

## THE EFFECT OF OXYGEN ON THE CLEAN UP OF PHOSPHORUS VAPOUR BY TUNGSTEN FILAMENTS.

BY H. W. MELVILLE AND S. C. GRAY.

*Received 27th April, 1936.*

The kinetics of the clean up of phosphorus vapour by hot tungsten filaments have been described in a previous paper.<sup>1</sup> It appears that the mechanism of the reaction is the dissociation of  $P_4$  molecules into  $P_2$  molecules on the tungsten surface, the  $P_2$  molecules then condensing to red phosphorus on diffusing to and striking the walls of the containing vessel. The present paper is concerned (*a*) with the effect of oxygen on the dissociation of  $P_4$  molecules on tungsten, and (*b*) with an attempt to determine the nature of the heterogeneous reaction on tungsten which initiates chains in  $P_4 - O_2$  mixtures.<sup>2</sup>

These latter experiments were mainly concerned at that time with establishing the essential features of this type of heterogeneous-homogeneous reaction, the heterogeneous part of which is zero order with respect to the phosphorus and oxygen concentrations. It was pointed out, however, that it is not possible for the chain initiator to be atomic oxygen nor an oxide of tungsten on account of the low filament temperature (max.  $750^{\circ}$  K.). The following possibilities are still open:—

(*a*) The  $P_4$  molecule collides with the tungsten surface, which may or may not have been affected by the addition of oxygen and dissociates

<sup>1</sup> Melville and Gray, *Trans. Faraday Soc.*, 1936, **32**, 271.

<sup>2</sup> Melville and Ludlam, *Proc. Roy. Soc., A*, 1932, **135**, 315.

into two  $P_2$  molecules. These latter react with oxygen thereby starting the chain. The rate of the initiation reaction would therefore be first order with respect to the phosphorus pressure, since the dissociation is also a first-order reaction.

(b) Phosphorus and oxygen are both strongly adsorbed on tungsten, and react together, giving rise to a lower oxide of phosphorus, which evaporates and reacts with the oxygen to initiate the chain. The conditions before evaporation may be regarded diagrammatically as

(c) The tungsten surface is completely covered with a film of oxygen atoms which prevents dissociation of  $P_4$  molecules. The latter, however, are adsorbed on top of the oxygen, and occasionally the  $P_4O$  complex evaporates, the empty space being immediately occupied by another oxygen atom. This may be represented as  $\text{W}-\text{O}-\text{P}$ .

(d) The inverse of (c). Phosphorus is so strongly adsorbed on tungsten that oxygen does not displace it, but is adsorbed on top. The evaporation of a lower oxide again initiates the chain:  $\text{W}-\text{P}-\text{O}$ .

**Experimental.**—The apparatus was identical with that used previously, the only addition being an oxygen reservoir. The Pirani gauge was separately calibrated for oxygen.

### Results and Discussion.

The first point to be considered is the activity of a deliberately oxidised tungsten filament towards the dissociation of  $P_4$  molecules upon it. In a reaction vessel of 157 c.c., fitted with a filament 0.1 mm. in diameter and effective length 90 mm., the half-life of phosphorus vapour at a pressure of 0.0194 mm. and temperature 635° C. was 3.5 min. On pumping out the phosphorus, admitting oxygen to 0.05 mm. pressure and heating the filament to 830° C., the oxygen pressure fell to 0.043 mm. The oxygen was pumped out and phosphorus admitted. The clean up could not be measured, there being no detectable pressure change ( $10^{-4}$  mm.) in 7 min. The filament had to be heated in vacuo to 1800° C. for 30 min. before the half-life of the phosphorus vapour returned to its previous value — 3.4 min. Heating the filament in 0.04 mm.  $O_2$  for 3 min. at 830° again inhibited the dissociation of the  $P_4$  molecules, the activity being completely restored on heating the filament to 1800° for 40 min. These experiments show immediately that covering the tungsten with a film of adsorbed oxygen atoms<sup>3</sup> completely inhibits the dissociation of  $P_4$  molecules, since the cause of inhibition is only removed at temperatures above 1800° C. This constitutes further evidence, in addition to that cited in the previous paper, that the dissociation is a specific chemical reaction.

The next sequence of experiments was carried out to answer the following questions:—

(1) Does the tungsten become appreciably oxidised if heated in oxygen alone to a temperature at which clean up of  $P_4$  is normally measured?

(2) Does the surface of the tungsten become oxidised as a result of the occurrence of the heterogeneous reaction responsible for starting chains in  $P_4$  —  $O_2$  mixtures?

(3) Is it possible to dissociate  $P_4$  molecules on an oxygen covered tungsten surface at a high enough temperature?

<sup>3</sup> Cf. Langmuir and Villars, *J. Amer. Chem. Soc.*, 1932, **53**, 486; Roberts, *Proc. Roy. Soc., A*, 1935, **152**, 400.

The tungsten filament was first cleaned by heating to  $1800^{\circ}\text{C}$ . for 40 min. At a filament temperature of  $635^{\circ}\text{C}$ ., the half-life of phosphorus was 6.0 min. 0.0178 mm. of oxygen were added and the tap connecting the reaction vessel and the phosphorus reservoir kept open in order to maintain the pressure of phosphorus vapour at a constant value during the run. After 20 min. 0.012 mm.  $\text{O}_2$  had been used up. The half-life of oxygen was therefore 15 min., since the rate of oxidation is first order with respect to the oxygen pressure,<sup>3</sup> which is more than twice that of the phosphorus at the same filament temperature. The reaction vessel was pumped out and a run with phosphorus yielded a half-life of 5.9 min. 0.0234 mm.  $\text{O}_2$  were then admitted alone to the reaction tube. The pressure fell to 0.0299 mm. after keeping the filament at  $635^{\circ}\text{C}$ . for 21 min. The oxygen was pumped out and it was found that the half-life of the phosphorus had increased to 11.2 min. After heating the filament to  $1800^{\circ}$  for 36 min. in vacuo the half-life returned to 4.8 min. The filament was once more poisoned. The temperature was then raised and at  $890^{\circ}$  the half-life of the phosphorus was 1.8 min., the calculated value for a clean filament being 0.06 min. On reducing the temperature to  $635^{\circ}$ , the half-life could not be measured. Finally, heating the filament to  $1800^{\circ}$  restored its former activity the half-life of phosphorus returning to the value 6.1 min. at  $635^{\circ}$ .

The conclusions to be drawn from these experiments are the following. Oxygen may poison the filament at temperatures normally used for cleaning up phosphorus, but when phosphorus vapour is present and the chain reaction between  $\text{P}_4$  and  $\text{O}_2$  proceeds, the filament is in some way not subject to attack. The possibility of starting chains by reactions (b) and (c) is therefore ruled out. In order to explain the fact that phosphorus prevents oxidation of the filament, it would be necessary to assume that at these temperatures, phosphorus is more strongly adsorbed on tungsten than is oxygen. Again, since the rate at which oxygen disappears is less than that at which  $\text{P}_4$  molecules are dissociated, the chains cannot be started by  $\text{P}_4$  molecules, for, in this circumstance, the rate at which oxygen would be consumed would be equal to the rate of dissociation multiplied by the chain length which is about 5 under the experimental conditions employed above.<sup>4</sup> That is, the half-life of oxygen would have been 1.2 min. compared with 15 min. observed. These experiments rule out scheme (a) on p. 1020. It seems, therefore, that (d) is the only possible mechanism, namely that the orientation of the phosphorus-oxygen layers each of which must be saturated to conform with the zero order of the reaction, is diagrammatically  $\text{W}-\text{P}-\text{O}$ .

#### The Interaction of Phosphorus Vapour with an Oxygen-Covered Filament.

With the clean filament the half-life of phosphorus vapour was 5.9 min. On heating to  $850^{\circ}$  in oxygen at 0.0404 mm. for 10 min. the oxygen pressure fell to 0.0174 mm. Table I. shows the sequence of runs carried out with the filament in this condition.

First the temperature had to be raised to  $1300^{\circ}\text{K}$ . before appreciable clean up could be measured. At  $1030^{\circ}$  it was faster, but on returning to  $1273^{\circ}$  the half-life had fallen from 5.8 to 0.9 min., showing that part of the oxygen film is removed, but not sufficiently to allow of the half-life being measured at  $908^{\circ}$ . As may be seen from experiments 5-11, when the temperature is maintained at  $1163^{\circ}$  the half-life decreases at each run showing that the oxygen film is being progressively removed. Even eight runs at  $1163^{\circ}$  are not sufficient to remove the oxygen, since in experiment 11 the half-life is greater than 60 min. Sufficient oxygen had been removed to permit of the half-life being measured at  $993^{\circ}$  and a series of experiments (12-19) carried out in the neighbourhood of this temperature showed

that several clean up experiments could be made without affecting the oxygen layer very much. A further series of experiments is shown in Fig. 1, where  $\log_{10} \epsilon$  is graphed against  $1/T$ ;  $\log_{10} \epsilon$  is the efficiency of collisions of  $P_4$  with the surface resulting in dissociation.

It will be observed that there is not much systematic deviation of the points from the line, and hence oxygen is not removed from the surface of the tungsten. The numbers refer to the order in which the runs were made. The slope of the line corresponding to an apparent energy of activation of 27 k. cal. On the same diagram the  $\log_{10} \epsilon - 1/T$  curve is shown for a clean filament, the slope of the curve in the temperature region employed in the above experiments corresponding to an apparent energy of activation of 30.0 k. cal.

FIG. 1.

It therefore appears likely that any clean up by a partially covered oxygen surface is due mainly to the dissociation of  $P_4$  molecules on bare portions of the tungsten. Assuming this to be the case, a calculation may be made of the fraction of the surface which is clean, in the following way. From the upper curve of Fig. 1 the half-life for the clean up at any temperature may be calculated if it is measured at only one temperature. The values ( $t_1''$ ) for the present system are shown in column 4 of Table I. The ratio of the value on a clean surface ( $t_1''$ ) to that on a partially oxidised surface ( $t_1'$ ) is shown in column 5. This, then, is the fraction of the surface free from oxygen. It will be seen that the extent of the clean surface gradually increases at temperatures above 1100°, whereas at 950° the fraction of the surface clean remains substantially

constant. An approximate estimate may also be made of the collision efficiency for the removal of oxygen atoms by  $P_4$  molecules. In experiments  $5.11 t_{\frac{1}{2}}''/t_{\frac{1}{2}}'$  increased from 0.009 to 0.081, which corresponds to the removal of  $9.2 \times 10^{12}$  atoms of oxygen, since there are  $4 \times 10^{14}$  atoms per  $\text{cm}^2$  in a complete film. During this time, about 0.1 mm. of  $P_4$  vapour was cleaned up. The total number of collisions of  $P_4$  with the oxygen covered surface is, assuming a mean pressure of 0.015 mm., and a total time of 24 min.,  $1.1 \times 10^{21}$ , yielding a collision efficiency of  $8.4 \times 10^{-9}$ , compared with  $4 \times 10^{-2}$  for the dissociation of  $P_4$ . At  $1300^\circ$  the number of O atoms removed by  $4.7 \times 10^{19}$  colliding molecules of  $P_4$  is  $3.9 \times 10^{12}$ , the collision efficiency being therefore  $8.3 \times 10^{-8}$ . The temperature coefficient for the removal of O atoms thus corresponds to an energy of activation of 46 k. cal., which is considerably greater than that for the clean up on a bare surface.

If these assumptions are true, then the  $P_4$  clean up may be used to measure the fraction of a tungsten surface which is bare when the greater part of it is covered with oxygen. Such a method is complementary to that in which caesium is employed to detect the presence of small amounts of oxygen on a relatively bare surface.<sup>5</sup>

#### Further Experiments on the Hetero-homogeneous $P_4 - O_2$ Reaction.

The next experiments were made to find what effect the unifilm of oxygen atoms had on the initiation of chains in  $P_4 - O_2$  mixtures. With the clean filament the half-life of the  $P_4$  at  $635^\circ \text{C.}$  was 6.7 min. The hetero-homogeneous reaction was followed in a manner slightly different from that used previously. Oxygen was admitted first, followed by the phosphorus and the pressures measured on the Pirani gauge. At the end of the run the  $P_4$  was condensed out, the  $p_{O_2}$  measured,  $O_2$  pumped out,  $P_4$  evaporated and its pressure determined. The data are given in Table II., two clean up runs being made in between the oxidation experiments to make sure no oxidation of the filament had occurred.

TABLE II.

## TIME OF EXPERIMENT, 32 MIN.

$O_2$ initial	0.0147	$P_4$ initial	0.0140
$O_2$ final	0.0049	$P_4$ final	0.0026
$t_{\frac{1}{2}}(O_2)$	9 min.	$t_{\frac{1}{2}}(P_4)$	13.2
$O_2 : P_4$ (used)		0.95 : 1	
$t_{\frac{1}{2}}$ for clean up at $635^\circ \text{C.} \approx 5.7$ min.			

## TIME OF EXPERIMENT, 33 MIN.

$O_2$ initial	0.0181	$P_4$ initial	0.0087
$O_2$ final	0.0040	$P_4$ final	0.0024
$t_{\frac{1}{2}}(O_2)$	14.2	$t_{\frac{1}{2}}(P_4)$	17.8
$O_2 : P_4$ (used)		2.24 : 1	

The first point to note is that no appreciable poisoning of the filament occurs during an oxidation run, second, the half-life of the oxygen is much greater than that of the clean up, and finally the  $O_2 : P_4$  ratio of the reacting gases is lower than that corresponding to the formation  $P_4O_{10}$ , or even of  $P_4O_6$ . The lower the phosphorus pressure, however, the higher is this ratio. In addition to the oxidation, there is considerable deposition of red phosphorus which means that besides supplying molecules to initiate the chains, the tungsten can still catalyse the dissociation of  $P_4$  molecules.

<sup>5</sup> Langmuir and Villars, *J. Amer. Chem. Soc.*, 1931, **53**, 495.

If it be assumed that the trioxide is formed in the first experiment,<sup>6</sup> then the  $O_2:P_4$  ratio should be 3:1, which would imply that about 60 per cent. of the  $P_4$  molecules which are used up are deposited as red phosphorus. From these results a maximum value for the collision efficiency of the reaction  $P_4 + O_2$  may be computed. The probability of a  $P_4$  molecule reaching the walls is  $e^{-L/\lambda}$ , where  $\lambda$  is the mean free path and  $L$  is the distance the molecules diffuse in the mixture, namely 1 cm. The mean pressure during the experiment is 0.02 mm., and if the mean free path is taken to be 3 mm.  $e^{-L/\lambda} = 0.037$ , i.e., only 3.7 per cent. of the  $P_4$  molecules reach the walls without making a collision with  $O_2$ . Taking the diffusion coefficient of the mixture to be  $5.7 \times 10^5$  cm<sup>2</sup>/sec., and the mean velocity of the molecules  $4 \times 10^4$  cm./sec., then the number of collision on diffusing to the walls is about 20, which therefore limits the collision efficiency to a maximum value of 0.05. The higher the pressure of the oxygen the smaller is the probability of red phosphorus being deposited on the walls, as is seen by the fact that the  $O_2:P_4$  ratio increases to 2.24.

On poisoning the filament once more by heating to 830° C. for 3 min. in presence of 0.05 mm.  $O_2$ , the half-life could not be measured, nor could any oxidation ( $< 10^{-4}$  mm.) be detected in 11 min. at 635° C. Heating the filament in vacuo to 1800° C. restored its former activity, the half-life of phosphorus being 5.9 min. Hence, not only does a film of atomic oxygen inhibit the dissociation of  $P_4$  molecules, but also the formation of molecules requisite for initiating chains. At high enough temperatures—830° C.—even an oxygen covered filament cleans up both  $P_4$  and  $O_2$ , but the fraction of the reaction which goes by way of chains was not measured.

### Summary.

The effect of oxygen on the clean up of phosphorus vapour by hot tungsten filaments has been investigated with the following results.

Covering a filament with a layer of O atoms completely inhibits the dissociation of  $P_4$  molecules upon it. At high enough temperatures an oxygen covered filament catalyses the dissociation, the oxygen film being simultaneously removed. At lower temperatures the oxygen film is no longer removed, a fact which permits a determination of the apparent energy of activation for clean up. This agrees with that for a clean filament, and hence it is concluded that the dissociation on a partially oxidised filament occurs wholly on the clean tungsten surface.

Further investigation has also been made of the hetero-homogeneous reaction between  $P_4$  and  $O_2$  in presence of tungsten. Measurement of the half-life for the  $P_4 - O_2$  reaction and for the  $P_4$  clean up, show the former to be much slower thus excluding the hypothesis that chains are started by the  $P_2$  molecules from the dissociation of  $P_4$ . Covering the tungsten with a unilam of O atoms also inhibits the oxidation. At the temperatures used in these experiments, about 700° C., oxygen alone rapidly covers the surface with oxygen atoms. In presence of phosphorus, however, this poisoning is practically prevented. It is therefore concluded that in the  $P_4 - O_2$  reaction the tungsten surface is covered with a layer of phosphorus, on top of which are oxygen atoms or molecules. The evaporation of a lower oxide from this composite layer initiates the stable chain reaction.

One of the authors (H. W. M.) is indebted to the Royal Commissioners for the Exhibition of 1851 for a Senior Studentship during the tenure of which these experiments were carried out.

# THE VAPOUR PRESSURE OF RED PHOSPHORUS.

BY H. W. MELVILLE AND S. C. GRAY.

*Received 27th April, 1936.*

The vapour pressure of a substance may be determined by two general methods, (a) direct manometric measurement of the pressure when the material is enclosed in a box, a variation of this method of especial importance at low pressures is to measure the rate of effusion of the vapour from a small hole in the box; (b) determination of the rate of evaporation *in vacuo* and subsequent calculation of the vapour pressure by means of the effusion equation, assuming that the condensation coefficient of the molecules or atoms is unity. Where comparison can be made these methods give results in agreement, provided that complications due to association or dissociation of the vapour are absent. When there are abnormalities of this nature a comparison of the two methods may then give some clue as to the mechanism of condensation and evaporation occurring at the interface.

The vapour pressures of (red) phosphorus, arsenic and to a smaller extent antimony are abnormal in the sense that the value of Trouton's constant calculated from the vapour pressure is unusually high, e.g., 37.4 for red phosphorus. Alternatively the vapour pressures are high compared with those calculated from the latent heat of vaporisation and using Trouton's constant to compute the integration constant of the vapour pressure equation. The vapour pressure of white phosphorus however is normal. From density measurements the vapour above white and above red phosphorus consists of  $P_4$  molecules, which would imply that  $P_4$  molecules condense on and evaporate from the surface of red phosphorus. In another paper<sup>1</sup> it has been shown that if  $P_2$  molecules impinge on a red phosphorus surface they condense to form red phosphorus, no combination to  $P_4$  occurring. It was also suggested that  $P_2$  molecules evaporate from red phosphorus. The explanation of the abnormally high vapour pressure is then simply that in a closed system  $P_2$  molecules evaporate from red phosphorus but as they accumulate the  $P_4 \rightleftharpoons 2P_2$  equilibrium is established and since this lies almost wholly on the  $P_4$  side, the observed pressure is mostly due to  $P_4$  molecules.

The object of the present paper is to show that only  $P_2$  molecules evaporate from the surface of red phosphorus *in vacuo* and that computation of the vapour pressure employing the molecular distillation technique gives values much lower than those obtained by the static method, this in turn yielding a more normal value for the Trouton constant. As will be seen below these expectations are realised and hence the conclusion is that only  $P_2$  molecules are concerned in the evaporation and in the growth of red phosphorus.

## Experimental.

The apparatus used consists essentially of two parts: one (I.) in which the phosphorus deposit is prepared and the other (II.) in which evaporation is carried out. The arrangement for deposition is shown in Fig. 1 and in

<sup>1</sup> Melville and Gray, *Trans. Faraday Soc.*, 1936, **32**, 271.

detail in Fig. 1*a*. A tungsten filament F is placed opposite the plate holder P. The glass plate upon which the red phosphorus is deposited is carried in this nickel wire holder. In order to define precisely the area of deposit a mica screen with a rectangular opening is fixed on the side of the plate facing the filament. Preliminary experiments showed that if the red phosphorus were deposited on a smooth glass surface then on heating in the apparatus in Fig. 2 the film invariably peeled off. This difficulty was overcome by lightly grinding the plate when the phosphorus formed a strongly adherent layer. Apparatus II. is essentially a pyrex bulb of 750 c.c. fitted with a re-entrant tube with a flat bottom on to which the phosphorus was received. This was partially filled with liquid air. About 1 cm. from the surface of the liquid air trap, the furnace for carrying the glass plate was supported by two 1 mm. nickel wires which also served to carry the current for heating the furnace. A support S kept the furnace assembly in position. The current leads finally passed out at a pinch seal which also carried the leads for the small platinum-platinum-rhodium thermocouple. The details of the construction of the furnace are shown diagrammatically in Fig. 2*a*. A flat iron plate 25 × 15 × 2.5 mm. served as a base on which the glass plate rested.

FIG. 1.

FIG. 2*a*.

The wires were 0.05 mm. thick and the junction itself was enclosed in a minute glass bead just sufficient to coat the wires. It was held in position by a molybdenum spring. Many attempts were made to fuse the glass bead

FIG. 2*b*.

containing the junction on to the glass plate, in order to obtain good thermal contact, but this was always attended by cracking of the plate once the temperature of the furnace was raised to about 400° C. The e.m.f. of the

couple was measured by a millivoltmeter. The construction of the furnace in this way gave a fairly even distribution of temperature over the surface of the plate according to visual observation when it was run red hot. It will be seen from the diagrams that the red phosphorus deposit only occupies the central portion of the plate. However, an exploration of the surface temperature was made by placing the thermocouple at various positions in the area occupied by the red phosphorus with a fixed current in the furnace windings. Even at the edge of the glass plate, the temperature was not more than  $5^\circ$  lower than that at the middle. Evaporation (runs) carried out with the couple in different positions gave the same values for the vapour pressure. In one or two of the distillations there was evidence that some white phosphorus was produced and it therefore became necessary to estimate its weight. For this purpose a glass spring gauge and an oxygen reservoir was attached to the evaporation bulb in order that a small quantity of oxygen could be admitted and the absorption by the oxidation of the white phosphorus noted.

This was the final form of the apparatus. The following arrangements were tried but were discarded. A movable filament system was introduced into the evaporation bulb in order to deposit the red phosphorus on the plate without having to remove the glass plate. This was unsatisfactory because the red phosphorus was sometimes deposited on the sides of the bulb and on the liquid air trap itself. The plate was also heated by radiation using a furnace consisting of several spirals of tungsten backed by a nickel reflector. Temperature control was difficult, the wire having to be run at  $2000^\circ\text{C}$ . and the whole bulb got unduly hot. Attempts to use a bifilar suspension for observing the change in weight of the plate were also abandoned.

### Results.

The procedure for carrying out a run was as follows: A clean ground plate (weight  $0.1-0.2\text{ gm.}$ ) weighed on a micro-balance to  $10^{-5}\text{ gm.}$  was fixed in the holder shown in Fig. 1*a* and inserted in the deposition apparatus. After pumping out for several hours, phosphorus vapour was admitted to a pressure of  $0.02\text{ mm.}$  and the deposition commenced by heating the filament. Deposition of  $1\text{ mgm.}$  on  $1\text{ cm.}^2$  required about 12 hours, the pressure of phosphorus being maintained at  $0.02\text{ mm.}$  The plate was then removed and weighed. To make sure that no appreciable volatilisation of the phosphorus occurred and also that no oxidation had taken place during its transference from apparatus I. to II., the plate was reweighed 24 hours afterwards. Invariably the weight was within  $10^{-5}\text{ gm.}$  of that previously recorded. Had there been evaporative..., there would have been a decrease in weight; oxidation would have led to an increase.

The furnace having been previously outgassed, the plate was placed in position and after evacuation of the bulb, liquid air was run into the tube. During evaporation, which occupied 1 to 3 hours, the pressure in the bulb did not rise above  $10^{-4}\text{ mm.}$  The mean free path of the  $\text{P}_2$  molecule is about  $50\text{ cm.}$  at this pressure and since the molecule has only to traverse a distance of  $1\text{ cm.}$ , the chance of its colliding with other molecules on the way is small. Reweighing the plate completed the experiment.

Experiments were also made with blank plates to make sure that the plate itself did not decrease appreciably in weight. The weight of the plate was about  $0.2\text{ gm.}$  At the highest temperatures a decrease of  $1-2 \times 10^{-5}\text{ gm.}$  was the largest recorded.

Another check, though less accurate, was made in the following way. A small circular deposit,  $3\text{ mm.}$  in diameter was formed on the plate and the evaporation carried out in the usual manner. On account of the cosine law of evaporation, the deposit on the liquid air-cooled surface thins out towards the edges with the result that a set of Newton's rings develops on the liquid air-cooled surface. Four rings could be observed and from their diameter an approximate estimate could be made of the weight of

the red phosphorus collected, assuming the refractive index to be 1.5. This agreed within 25 per cent. of that determined by direct weighing. Furthermore this allowed of a continuous observation of the rate of evaporation.

Typical results are shown in Table I. Experiments 4 and 7 were second evaporations from the same plate. The vapour pressures in the sixth column of the Table were calculated from the Herz-Knudsen equation

$$p = 17.4 \sqrt{\frac{T}{M}} \cdot m$$

where  $p$  is the pressure in millimetres of mercury,  $M$  is the molecular weight of the vapour and  $m$  the mass in grams evaporating per sec. per  $\text{cm}^2$  of surface. The following two assumptions were made (a) that the condensation coefficient of  $\text{P}_4$  molecules on red phosphorus is unity, and (b) that the effective surface is equal to the projected geometrical surface. The vapour pressure of red phosphorus determined by the static method is computed from the formula

$$\log_{10} p(\text{mm.}) = -\frac{5610}{T} + 11.061.$$

It will be observed that the new values are considerably lower than the older data, which is in accordance with the introductory statements. In Fig. 3,  $\log_{10} p$  (mm.) is plotted against  $1/T$ , this giving a straight line with a slope corresponding to an energy of evaporation of 20 kg. cal.—not much lower than 25.6 kg. cal. from the temperature coefficient of the pressure of  $\text{P}_4$  molecules above red phosphorus. The extrapolation required to calculate Trouton's constant from the new data is so large that no quantitative use could be made of the calculation. In a qualitative way however it is obvious that the smaller vapour pressures would give a smaller value for Trouton's constant than that (37.4) derived from the data quoted in the last column of Table I.

FIG. 3.

TABLE I.

No. of Experiment.	Temperature of Evaporation, °C.	Area of Evaporation, $\text{cm}^2$ .	Weight Evaporation, gm.	Time of Evaporation, min.	Vapour Pressure, mm.	Vapour Pressure Static Method, mm.
1	480	1.12	0.00049	8	$5.5 \times 10^{-6}$	3490
2	410	1.12	0.00046	60	$6.6 \times 10^{-6}$	630
3	400	1.20	0.00048	60	$6.4 \times 10^{-6}$	480
4	400	1.20	0.00066	60	$8.8 \times 10^{-6}$	480
5	350	1.20	0.00022	62	$2.7 \times 10^{-6}$	102
6	350	1.20	0.00028	62	$3.5 \times 10^{-6}$	102
7	350	1.20	0.00010	21	$3.6 \times 10^{-6}$	102
8	305	1.12	0.00016	124	$1.0 \times 10^{-6}$	21.5

After some of the evaporations, oxygen was admitted to the evaporation bulb, the tap to the pump having been closed and the liquid air allowed to evaporate. Sometimes a momentary flash due to the oxidation of white phosphorus was obtained, but the amount of oxygen consumed indicated that less than 5 per cent. of the total phosphorus evaporated consists of  $P_4$  molecules. The presence of white phosphorus was most pronounced when the evaporation was carried out with a clean liquid air-cooled surface. After the latter had become covered with red phosphorus practically no white modification could be detected. It would seem therefore that only a fraction of the  $P_2$  molecules tend to combine on striking a glass surface. This is in agreement with previous observation on the clean-up of phosphorus vapour. Reproducible and constant results were only obtained when the surface of the reaction vessel had become covered with a uniform film of red phosphorus.

### Summary.

A redetermination of the vapour pressure of red phosphorus has been made by evaporation in a vacuum. Application of the Herz-Knudsen effusion equation to the results gives values for the vapour pressure about  $10^7$  times lower than the normal static method. The new values are given by the equation

$$\log_{10} p \text{ (mm.)} = -\frac{4110}{T} + 1.1.$$

The reason for the discrepancy is due to the fact that although  $P_2$  molecules condense on and evaporate from red phosphorus, the equilibrium  $P_4 \rightleftharpoons 2P_2$  is set up in a closed system. At temperatures normally employed the equilibrium is almost wholly on the  $P_4$  side and hence in the static method the pressure is due almost wholly to  $P_4$  molecules. In the molecular distillation method no opportunity is given to the molecules to combine to  $P_4$  and therefore the apparent vapour pressure is much smaller.

### Erratum.

In the first paper of this series<sup>1</sup> the heat of transformation of white to red phosphorus was erroneously taken as 4 kg. cal. per gram molecule ( $P_4$ ) whereas in fact this value refers to the gram atom. This alters slightly the calculation of the heat of desorption of  $P_2(\lambda_p)$  from red phosphorus, see page 274 *loc. cit.*<sup>1</sup> Taking the heat of dissociation of  $P_4$  to  $2P_2$  to be 30 kg. cal. then

$\lambda_{p_2} = 29.8$  kg. cal. from the thermo chemical cycle

and 27.9 kg. cal. from the apparent heat of evaporation of red phosphorus.

The corresponding values if  $P_4 \rightarrow 2P_2$  is 50 kg. cal. are 39.8 and 37.8 kg. cal. respectively. The agreement between the two methods of calculation is even better than that formerly obtained.

The authors are indebted to Professor E. K. Rideal and Dr. E. B. Ludlam for critical discussions during the progress of this work. One of them (H. W. M.) thanks the Royal Commissioners for the Exhibition of 1851 for a Senior Studentship. The experiments were made in the Chemistry Department of the University of Edinburgh.

# KINETICS OF SIMULTANEOUS POLYMERISATION AND RING FORMATION.

By M. STOLL.

Received 6th May, 1936.

In a recent article<sup>1</sup> on this subject, it was stated that the velocity constant  $k_1$ , measured between the limits of 10 and 70 per cent. conversion, corresponds to the purely monomolecular ring closure reaction, even though 25-35 per cent. of polymers are formed at the reaction. This conclusion is based on a second statement, unsupported by any experimental data, according to which "the essential part of the secondary polymers is formed between the limits of 60 and 100 per cent. conversion."

In contrast to this, we have shown, as a result of numerous experimental researches described and discussed in detail elsewhere,<sup>2</sup> that the determination of the velocity constant in a monomolecular ring-closure reaction (on the basis of changes in the functional groups and in those cases where it leads to rings of more than six members) is unequivocal *only if no polymers* can be traced, even if the reaction seems to be a first order reaction with a velocity independent of the initial concentration.

A reaction of the first order, or a reaction velocity independent of the initial concentration is, therefore, no proof at all that the reaction has proceeded as in infinite dilution. On the contrary, it seems to be typical of ring-closure reactions that, between the limits of 10 and 70 per cent. conversion, they are always of the first order, even if they depend on a previous bimolecular reaction.<sup>3</sup>

The velocity of polymerisation cannot, moreover, be estimated from a graphic representation of the reaction velocity; for, if the polymerisation is a primary one, it can only take place at the beginning of the reaction, up to about 10 per cent. conversion.<sup>4</sup> At this stage, however, the chances of error are highest and graphical appreciation is therefore inaccurate. If, in addition, a secondary polymerisation should occur, even this approximate appreciation becomes impossible. On the one hand, the primary polymerisation, as several experiments have shown, tends to reduce the reaction velocity after 10 per cent. conversion<sup>4, 5</sup> and, on the other hand, the secondary polymerisation (which, as we seek to prove below, reaches its highest velocity at about 50 per cent. conversion) increases the velocity between 30 and 70 per cent. conversion. In these circumstances, any attempt at determining the velocity constant graphically, must be considered illusory.

<sup>1</sup> G. Salomon, *Trans. Faraday Soc.*, 1936, **32**, 169.

<sup>2</sup> M. Stoll, A. Rouvé and Stoll-Comte, *Helv.*, 1934, **17**, 1289; 1935, **18**, 1087.

<sup>3</sup> M. Stoll and A. Rouvé, *Helv.*, 1936, **19**, 253.

<sup>4</sup> *Ibid.*, 1935, **18**, 1097.

<sup>5</sup> *Loc. cit.*,<sup>3</sup> page 1297, Table III.

Consider the case <sup>6</sup> where the ring closure product B reacts with the starting material A, and forms a secondary polymer AB. The velocity of this secondary polymer reaction,  $\frac{dC_{AB}}{dt}$ , will depend on the concentration of the starting material  $C_A$  and on the concentration of the ring closure product  $C_B$ ,  $\frac{dC_{AB}}{dt} = k_3 \times C_A \times C_B$ . The velocity will be highest when the product of the two concentrations reaches a maximum. Since  $C_A + C_B = 100 - C_{AB}$ , this will be the case when

$$50 \geq C_A \geq \frac{100 - C_{AB}}{2} \geq C_B.$$

If the maximum should occur at 60 per cent. conversion, then the concentration of the secondary polymers must have reached 20 per cent. of the starting material. *Moreover, if the reaction yields (at complete conversion) 25.35 per cent. polymers, then they have been mainly produced before 60 per cent. conversion (conversion =  $100 - C_A$ ).*

TABLE I.

$C_A$	$C_B$	$C_{AB}$	Difference.	$C_A \times C_B$	$100 - C_A$
100	0	0	—	0	0
87	10	3	3	870	13
72	20	8	5	1440	28
56	30	14	6	1680	44
50	34	16	2	1700	50
40	40	20	4	1600	60
25	50	25	5	1250	75
11	60	29	4	660	89
0	68	32	3	0	100

From this and from Table I. (which is merely schematic), it follows that the highest velocity of formation is found, not between the limits of

<sup>6</sup> In order to explain the formation of appreciable quantities of polymers AB during the cyclisation reaction of bromamines, G. Salomon <sup>1</sup> considers only one of the two possible reactions

We are of the opinion, that it is impossible by means of kinetic analysis to exclude entirely one or the other of the two reactions. It is most probable, that the two reactions proceed simultaneously, a fact which cannot be without its influence on the monomolecular velocity constant  $k_1$ .

60 and 100 per cent., but between 25 and 75 per cent. conversion. The velocity constant  $k_1$  measured between 10 and 70 per cent. conversion, therefore contains to a large extent also the velocity constant  $k_2$  of the secondary polymer reaction.

Moreover, if one takes into consideration the fact that the occurrence of a primary polymer reaction, which would take place mainly in the first phases of the reaction (0-10 per cent. conversion) cannot be excluded (for the reasons mentioned above)<sup>6</sup> it becomes clear that the velocity constant of a reaction in which an appreciable quantity of polymers is formed, cannot in any way be considered as representing the velocity constant of the monomolecular ring formation. There is therefore no sufficiently accurate foundation for any mathematical treatment or general consideration of the ring-closure problem (more especially the calculations of the Arrhenius constants)<sup>7</sup> based on such an assumption.

Knowing that it was practically impossible to obtain pure velocity constants for ring-closure reactions, we introduced some time ago<sup>8</sup> the "cyclisation constant," i.e. the quotient  $k_1/k_2$ , as a measure of the facility of ring formation.

If  $c$  is the concentration of the starting material, and  $Y$  the quotient (*monomeric ring-closure product*) / (total primary polymers) at complete conversion, then the cyclisation constant  $k_1/k_2$  is determined by the equation<sup>8</sup>

$$\lg\left(1 + \frac{c \cdot k_2}{k_1}\right) = \frac{Y \cdot c}{1 + Y} \cdot \frac{k_2}{k_1}$$

and can readily be obtained by a quantitative analysis of the reaction products. Again, in this case, however, the determination of the cyclisation constant, is limited to ring-closures for which the primary monomolecular reaction product is stable, and does not undergo any important transformation, as, for instance, do the cyclic imines.

*Research Laboratory of Chuit-Naef & Co.,  
Firmenich & Co. Successors,  
Geneva.*

<sup>7</sup> *Loc. cit.*<sup>5</sup> As the yield of the cyclisation of hexamethylenbromamine in 0.005 molar aqueous solution does not reach 100 per cent., it appears most probable that the too high activation constant  $Z_4$  (G. Salomon, *loc. cit.*<sup>1</sup>) is due, not to a particularly high probability of the ring position but, rather, to an "impure" monomolecular velocity constant, and this in spite of the concordance between the calculated and observed values.

## THE EXCHANGE OF DEUTERIUM BETWEEN DEUTERIUM HYDROXIDE AND ETHYL ALCOHOL.

BY W. J. C. ORR.

*Received 11th May, 1936.*

It has generally been supposed that the exchange reactions of deuterium between water and the alcohols are very rapid. Some preliminary calculations indicated that the rate might, in neutral solutions, be open to observation, and at the outset several attempts were made to follow

the progress of the reaction:  $C_2H_5OH + HOD \rightleftharpoons C_2H_5OD + HOH$  by means of such physical properties as refractive index, viscosity, and electrical conductivity in the presence of dilute acid. No significant changes were observed, from which it was concluded that either the change in property observed was very small, or the reaction very rapid. Attention was then turned to the determination of the equilibrium constant of the reaction and a method was developed in which a sample of the water from the equilibrium mixture was removed for analysis as  $CaSO_4$  hydrate. It was found in these experiments that the extent of the exchange varied with the time of contact prior to the addition of the  $CaSO_4$ , and it appeared that about 18 hours was required for the establishment of equilibrium at  $25^\circ C$ .

### Experimental.

**Procedure.**—Solutions of ethyl alcohol and 20 per cent. deuterium hydroxide were made up by weight in stoppered tubes and placed in a thermostat at  $25^\circ \pm .01^\circ C$ . To determine the concentration of deuterium in the water in a given mixture at a given time 3.4 grms. anhydrous  $CaSO_4$  was added which removed a fraction of HOD as hydrate. The hydrate was rapidly filtered on a sintered glass crucible, dry air being drawn through the precipitate for 45 minutes under a pressure reduction of about 40 mm. The  $CaSO_4 \cdot x$  HOD was then dehydrated at  $150^\circ$  for  $1\frac{1}{2}$  hours, and the liquid analysed. That no appreciable fractionation of HOD occurred in the above process<sup>1</sup> is shown in the following typical experiment. 4.40 grms.  $CaSO_4$  were added to 4.0 c.c. 20.4 per cent. HOD. 3.47 grms. of the hydrated salt were collected from which 1.05 c.c. HOD, of D-concentration 20.2 per cent., were obtained.

The formation of the hydrate is not instantaneous but takes place during 30 minutes so that the sample of water removed represents the average concentration of D in the water portion of the reacting mixture during this time.

The ethyl alcohol was dried for fourteen days over  $CaO$ , then two days over  $Ca$  and slowly distilled, a middle fraction boiling at  $77.2^\circ C$ . (760 mm.) being collected under anhydrous conditions for these experiments.

20 per cent. DOH, obtained by dilution of the I.C.I. 99.95 per cent. product was twice distilled and outgassed. The D-content of several samples was determined for calibration purposes (to within .01 per cent.) by density measurements using a 14.0 c.c. pycnometer.

A.R.  $CaSO_4$  was freshly dehydrated under reduced pressure at  $180^\circ C$ .

**Analysis.**—The yield of water to be analysed varied between 0.5–1.0 c.c. and usually contained traces of alcohol ( $< 0.4$  wgt. per cent.). In order to analyse the mixture for D in the presence of alcohol, density and interferometer measurements were made in co-operation. With a pycnometer of 0.45 c.c. capacity the D-content was given by the calibration equation (mol. per cent. D) =  $0.209 W (\pm 0.2)$ , where  $W$  is the difference, in 0.1 m. gm. units, of the weight of the pycnometer filled with a given sample of heavy water and when filled with ordinary water. The calibration equation for measurements with a 1 cm. cell of a Rayleigh Interferometer was (mol. per cent. D) =  $-0.0629 I (\pm 0.1)$  where  $I$  is the number of drum divisions shift when a heavy water sample is compared with ordinary water.

Calibration solutions of known quantities of alcohol in  $H_2O$  and in 18.6 per cent. HOD were made up, and the difference in density and interferometer reading compared with  $H_2O$  in the first case and 18.6 per cent. HOD in the second, were measured. These differences, plotted in Fig. 1, show that the addition of alcohol in a given proportion to  $H_2O$  and HOD (up to 18.6 per cent.) produces the same change both in density and inter-

<sup>1</sup> Cf. Day, Hughes, Ingold and Wilson, *J. Chem. Soc.*, 1934, 1593.

ferometer reading. Thus, since the addition of alcohol to water increases the refractive index and decreases the density, while the addition of HOD decreases the refractive index and increases the density, a unique value for the D-content can be found. If a sample of water containing EtOH gives

FIG. 1.

an interferometer reading  $I$ , and a density difference  $W$ , compared with ordinary water, then

$$(\text{mol. per cent. D}) = -0.0629 (I - x) = 0.209 (W - y)$$

where  $x/y = a/b = -19.2$ ,  $a$  and  $b$  being the slopes of the curves so labelled in Fig. 1.

### Results.

Initial Per Cent. HOD.	Wgt. EtOH grms.	Wgt. HOD grms.	Vol. of Soln. c.c.	Time of Reaction Hours.	$I$ Drum Divisions.	$W$ o'1 mgrms.	Equil. Per Cent. HOD.	Grm. mol./litre.				$\alpha$
								a.	b.	c.	x.	
21.74	3.3667	5.5172	9.44	2	-107.5	44	19.4	7.74	6.98	25.13	0.74	0.44
20.9	2.0664	3.9926	6.38	3.8	-84	40	18.0	7.04	7.18	27.17	0.97	0.72
20.9	3.7732	8.8250	13.16	6.8	-122	42	18.0	6.23	7.70	29.15	1.06	0.93

The exchange ratio,  $\alpha$ , in the above Table is defined as

$$\alpha = \frac{x(c+x)}{(a-x)(b-x)} = \frac{[\text{EtOD}][\text{HOH}]}{[\text{EtO}][\text{HOD}]},$$

where  $[\text{EtOD}]$ , etc., are the molecular concentrations of each species in the mixture at time  $t$ . Since there is a probable error of  $\pm 0.2$  mol. per cent. in the determination of the equilibrium D concentration the values of  $\alpha$  are uncertain to  $\pm 2$  per cent.

From Fig. 2, which shows the variation of  $\alpha$  with time, the equilibrium distribution  $\alpha_e = 1.11$ .

## Discussion.

In the reaction

the rate of formation of EtOD may be expressed analytically as follows :

$$\frac{dx}{dt} = k_1(a-x)(b-x) - k_2x(c+x) \quad (1)$$

At equilibrium  $\frac{dx}{dt} = 0$ ,

$$\therefore \frac{k_1}{k_2} = \frac{x(c+x)}{(a-x)(b-x)} = \alpha_e (= 1.11). \quad (2)$$

FIG. 2.

Substituting  $k_2\alpha_e$  for  $k_1$  in equation (1) and integrating gives the following result :

$$k_2 = \frac{2.303}{\beta(\alpha_e - 1)t} \log_{10} \frac{2\lambda - x(K - \beta)}{2\lambda - x(K + \beta)},$$

where

$$K = \frac{1}{\alpha_e - 1}[(a+b)\alpha_e + c]; \quad \lambda = \frac{1}{\alpha_e - 1}\alpha_e \cdot a \cdot b; \quad \beta = \sqrt{K^2 - 4\lambda}.$$

Since  $\alpha = \frac{x(x+c)}{(a-x)(b-x)}$ ,  $\alpha$  can be evaluated numerically as

a function of  $t$  when  $k_2$  is given a definite value. The curve drawn in Fig. 2 is that calculated from the above equations, the value  $k_2 = 2.2 \times 10^{-6}$  being chosen to give the best fit with the experimental points. Taking account of the possible error in the  $\alpha$ -values one has

$$\text{and from (2)} \quad \begin{aligned} k_2 &= 2.2 \pm 0.2 \times 10^{-6} \text{ (litres/grm. mol. sec.)} \\ k_1 &= 2.4 \pm 0.2 \times 10^{-6} \text{ (litres/grm. mol. sec.)} \end{aligned}$$

The order of magnitude of these figures appears to be roughly in accordance with what is to be expected if the initial step in the exchange reaction is an ionisation of the type

Assuming, in the first place, that the mixture of HOD and EtOH is ionised to the same extent as water, the concentrations of  $\text{OH}^-$  and

$\text{C}_2\text{H}_5\text{OHD}^+$  are  $10^{-7}$  gram. mols./litre, and HOD and EtOH, 55.5 and 17.1 gram. mols./litre respectively, then,

$$K = \frac{k_a}{k_b} = 1.05 \times 10^{-12}.$$

The activation energy of the recombination reaction may be expected to be small: if it be assumed to be zero, then  $k_b = z$ , where  $z$  is the collision factor for a bimolecular reaction, an average value of which is  $2.77 \times 10^{11}$  (litres/gram. mol. sec.).<sup>2</sup>

Hence  $k_a = 2.8 \times 10^{-6}$  (litres/gram. mol. sec.).

From the equilibrium value,  $\alpha_e$ , the ratio of the ionisation constants of EtOH and EtOD may be calculated, the equilibria involved being as follows:

From the above equations it is evident that

$$\frac{K_2}{K_1} \frac{K_3}{K_4} = \frac{[\text{EtOD}][\text{HOH}]}{[\text{EtOH}][\text{HOD}]} = \alpha_e = 1.11.$$

Now according to Abel, Bratu and Redlich,<sup>3</sup>  $\frac{K_3}{K_4} = 1 - 1.41x + 0.57x^2$ , where  $x$  is the mol. fraction of deuterium. In the present experiments  $x = 0.083$ , thus  $\frac{K_3}{K_4} = 0.89$  and  $K_2 = 1.25 K_1$ .

### Summary.

1. It has been found possible to measure the rate of exchange of deuterium between ethyl alcohol and deuterium hydroxide by using  $\text{CaSO}_4$  to remove samples of DOH from the reacting mixture.

2. The equilibrium constant,  $\alpha_e$ , of the reaction

is found to be  $= 1.11$ , the rates of the forward and backward reactions being

$$k_1 = 2.4 \pm 0.2 \times 10^{-6} \text{ (litres/gram. mol. sec.)}$$

$$k_2 = 2.2 \pm 0.2 \times 10^{-6} \text{ (litres/gram. mol. sec.)}.$$

These values are of the order expected theoretically on the grounds that the exchange proceeds ionically.

3. From the equilibrium distribution ratio,  $\alpha_e$ , the ratio of the dissociation constants of EtOH to EtOD in presence of 16 per cent. HOD is found to be 1.25.

I wish to thank Dr. J. A. V. Butler for suggesting this problem and for his advice and encouragement during the course of the work. I have also to express my gratitude to the Carnegie University Trust for a Scholarship, to the Moray Fund for a grant for the purchase of heavy water, and to Messrs. Imperial Chemical Industries for a grant by which the Interferometer was purchased.

## REVIEWS OF BOOKS.

**Flame.** By O. C. DE C. ELLIS and W. A. KIRKBY. (London, Methuen. Pp. vi + 106 + 15 figs. 3s. net.)

The Methuen Monographs on Chemical Subjects usually provide interesting fare and the present volume is not an exception. There are many aspects of the subject of flame and it is hardly possible for one individual to speak authoritatively on all of them. The authors direct their attention mainly to the behaviour of flame as an entity and to an examination of its various shapes and movements in many kinds of vessels. The phenomena occurring ahead of and behind the flame front are examined in considerable detail, and in their elucidation of these matters the authors have drawn on the wealth of experimental technique and data made available by the Safety in Mines Research Board. The authors' treatment of "afterburning" is of particular interest and contains much that is original. Ignition phenomena and the flame limits are thoroughly discussed but chemical mechanisms in the modern sense are dismissed in seven pages. There is, nevertheless, a good deal of novelty in the ideas presented, and the book is welcome if only for the clear account it gives of flame movement and associated phenomena in closed vessels. There is a valuable bibliography.

**Phenomena in High Frequency Systems.** By AUGUST HUND. (McGraw Hill, London, 1936; 594 pages, appendix, and index. Price, 36s.)

This book deals almost exclusively, but in great detail, with the theory of the generation, transmission, and reception of radio frequency currents. Except for the two chapters on the ionised upper atmosphere and piezo-electric phenomena, and a brief account of plasma oscillations, practically no reference is made to high frequency phenomena depending on the physical and chemical properties of substances for example, the variation of the dielectric constant and the dielectric loss with frequency.

R. W. L.

**Schwimmaufbereitung.** By W. PETERSEN. (Theod. Steinkopff, Dresden, 1936. Pp. xii and 300. Price, 18 RM; Bound, 19.50 RM.)

This is a very good book. The author has not hesitated to attack the difficult question of wettability and I hardly know of any equally clear exposition on interfacial tensions and their interaction, on adhesion, on the problems related to contact angles and their determination, to linear and laminar adsorption, etc. He also does not make the mistake, so frequently found in general treatises on flotation, of overrating one side of the phenomena involved and thus developing an "adsorption" or a "chemical" or an "electrical" theory of flotation; he bears in mind that all these factors, and others, come into play and does not forget that his task consists in giving a well-balanced description of these manifold effects and

their intricate connexions. Although Petersen is obviously keenly interested in the theoretical side of his subject, he by no means neglects experimental facts and thoroughly discusses a great number of collectors and frothers, many special problems in "mineral separation" and technical devices to effect flotation.

The flotation industry is in a pre-eminent position as depending on the fundamental importance of capillary chemistry and yet involving large capital expenditure. Nevertheless, physical chemists cannot boast that they were the first to introduce and devise these methods; they are almost entirely due to engineers. Surface chemistry has proved its value only in the surprising specialisation and subtlety which have been developed in recent years.

H. F.

**Review of Inorganic Chemistry.** By NIELS BJERRUM. (William Heinemann Ltd. Pp. vi + 317. 7s. 6d.)

Although this is intended to be an elementary text-book, it is one which can be read with pleasure and profit by any chemist, and so well has the translation been done that the reader does not feel that the book was not originally written in English.

In the reviewer's opinion, the book is not suitable for those who are just beginning the study of chemistry, but should be very useful to students who have already passed the intermediate stage. The reasoning is too close and concentrated for a beginner, and theories are stated somewhat too dogmatically and without sufficient reference to the experimental and historical foundations.

The book is admirable as a summary of modern chemical theory and of the more important facts relating to the commoner elements. The modern views of acids and bases are made clear and emphasised, as was to be expected, in a book emanating from Copenhagen. Most important theoretical matters are considered briefly and serious students of chemistry will find the book a helpful supplement to their lectures, but they must bear in mind that they will need to become acquainted with more of the hum-drum facts of chemistry than will be found in it.

**Introduction to Quantum Mechanics (with Applications to Chemistry).** By LINUS PAULING and E. BRIGHT WILSON. (McGraw-Hill Publishing Co., London, 1935. Pp. xiii + 468. Price 30s.)

**The Quantum Theory of Valency.** By W. G. PENNEY. Methuen's Monographs on Chemical Subjects. (Methuen & Co., Ltd., London, 1935. Pp. vi + 95. Price 2s. 6d.)

The Introduction to Quantum Mechanics, which has been written by Linus Pauling and E. Bright Wilson, fulfils a long-felt need. Its aim is to provide sufficient quantum mechanics to understand the advances which are now being made in the theory of chemical bonds. It does not demand an extensive knowledge of mathematics but it does assume that the reader is anxious to understand the mathematical applications of

quantum mechanics and is willing to follow the necessary steps in the argument if suitably presented. No better guide could be recommended to those anxious to study modern developments in theoretical chemistry.

The Schrödinger equation, the interpretation of wave function and the auxiliary restrictions placed upon it, are introduced as fundamental postulates—a series of working rules, from which results can be predicted and compared with experimental data. A number of simple examples are worked out, in particular the wave functions of the hydrogen-like atom. A thorough knowledge of these is indispensable to an understanding of electronic structure of atoms and molecules, for they are used as a basis for almost all applications of quantum mechanics to molecular problems. The standard methods of passing from simple known systems to other more difficult unknown systems involve the use of the perturbation theory and the variation method. These are described in detail and a number of informative and illuminating examples are worked out.

Two subjects of great importance are then dealt with: one the method of dealing with many electron atoms and the other the structure of simple and complex molecules. The important development made by Slater in the treatment of complex atoms is described in detail, and this not only shows how the multiple structure of atoms can be found but also prepares the way for the theory of valency links. The important concept of resonance, used extensively by Pauling in chemical phenomena, is described—but only briefly. Many readers would doubtless have welcomed a further discussion of this subject and more examples. The method of molecular orbitals is only briefly referred to. None the less the book brings the reader to the stage when he can understand recent developments and for this reason is likely to find an appreciative circle of readers. The reviewer thinks so highly of it as an introductory book that he has recommended it to all his students.

The monograph by Mr. Penney carries out the difficult task of putting into descriptive language the new ideas which are at the basis of the quantum theory of valency and does it with conspicuous success. The treatment is necessarily concise owing to the limited space available in a small monograph, and those readers who approach the subject for the first time must expect to take some parts of the book for granted (particularly in the chapter on "The Method of Localised Pairs"). A close reading of the book will, however, convey a very good idea of the successes and limitations of the present theory of valency.

J. E. L.-J.

## A GENERAL DISCUSSION ON DISPERSE SYSTEMS IN GASES; DUST, SMOKE AND FOG.

THE SIXTY-FOURTH GENERAL DISCUSSION OF THE FARADAY SOCIETY was held in the Department of Chemistry of the University of Leeds from the 20th to 22nd April, 1936, inclusive.

The subject was considered under two heads :—

Part I. : The General Properties and Behaviour of Disperse Systems, composed of :—

- (a) Solid and Liquid Non-Volatile Particles, *i.e.* Smoke, Dust, Oil Fogs, etc.
- (b) Aqueous and Other Volatile Particles, *i.e.* Mist, Cloud, Hygroscopic Nuclei, Town and Country Fogs.

Part II. : The Industrial Aspects of Disperse Systems in Air and Gases.

In the absence of the President, the Chair was occupied in succession by Sir Robert Robertson and Professor F. G. Donnan, Past Presidents.

By the courtesy of the Vice-Chancellor and the Refectory Committee, the Guest Night Dinner was held on Tuesday, 21st April, in the Refectory.

At the Inaugural Meeting, the Vice-Chancellor of the University, Sir James Baillie, welcomed the Society to Leeds, and Sir Robert Robertson then introduced the overseas guests, visitors and members, who were received with acclamation. The following were so welcomed : Professor J. Firket (*Liege*), Dr. E. Hiedemann (*Köln*), Professor H. Köhler (*Uppsala*), Dr. and Frau R. Meldau (*Berlin-Charlottenburg*), Dr. J. L. van der Minne (*Amsterdam*), Dr. J. J. Nolan (*Dublin*), Dr. E. Proskauer (*Leipzig*), Professor H. Remy (*Hamburg*), Dr. P. Schuftan (*München*), Dr. H. Schmeel (*Darmstadt*), and Dr. P. Siedler (*Frankfurt a.M.*).

At the conclusion of the meeting, the thanks of those present were accorded to the overseas guests, to the Vice-Chancellor and Senate of the University, to Professor Whytlaw-Gray, Mr. Cawood, and other members of the organising committee, to the Refectory Committee, and to the contributors of papers.

The Report of the meeting, including all the papers contributed, together with the discussion thereon, appears in the following pages.

## DISPERSE SYSTEMS IN GASES.

(General Introductory Paper.)

BY R. WHYTLAW-GRAY.

*Received 14th April, 1936.*

The subject of this discussion includes a great variety of natural and artificial systems which are described by such terms as dust, smoke, fog, fume, haze, mist and cloud. All these consist of solid or liquid material dispersed to a greater or lesser extent in gaseous media. They all show a great tendency to change and none are permanent when compared with the more familiar colloidal solutions. Thus dusts settle, smokes coagulate, and clouds dissipate by evaporation.

This characteristic instability is clearly a consequence of the physical properties of the gaseous medium, the low density and low viscosity of which offers little resistance to the movement of the particles or to molecular diffusion. Hence in these systems the particles sediment under gravity or centrifugal force, diffuse by brownian motion, and evaporate or dissolve at a much greater rate than they would were the medium liquid. It must be remembered, too, that the smaller particles suspended in gases possesses an enhanced mobility on account of the discontinuities in the medium. For example, the majority of smoke particles lie between the size limits  $5 \times 10^{-6}$  and  $5 \times 10^{-5}$  cm., radius, whilst the mean free path of the molecules in air at normal pressure is of the order of  $10^{-5}$  cms.

For the purposes of this meeting it is convenient to consider separately the behaviour of systems of non-volatile and volatile particles. To the former category belong most dusts and smokes and some industrial fogs such as tar fogs, and to the latter the majority of natural systems such as country fogs, mist, etc., in which the particles are composed of water or of dilute aqueous solutions of hygroscopic nuclei. It is obvious that there is no clear dividing line between these two classes. Thus a sulphuric acid cloud in dry air would belong to the former and in moist air to the latter, again the particles of tobacco smoke rapidly absorb moisture and those in town air contain hygroscopic as well as carbonaceous material so that they readily condense water when the conditions are favourable. But it is evident that in many respects systems of non-volatile particles are simpler and certainly easier to investigate than those in which evaporation and condensation are additional and complicating factors.

Moreover these systems of non-volatile particles have in recent years attracted the attention of scientific workers both abroad and in this country so that a short summary of their properties may serve as a focussing point for this discussion.

### Smoke.

Smoke is formed whenever the vapour of a substance of high boiling-point is diluted rapidly and cooled by admixture with a large volume

of air or any other gas. This method applies to many systems. Smokes can be formed also by chemical reactions at ordinary temperatures, indeed any reaction between gases or vapours resulting in the formation of a solid or liquid phase will when carried out in presence of a large excess of an indifferent gas produce a smoke. Smokes then are formed from molecularly disperse material, by condensation, and in its early stages the process presents an analogy to the formation of a gold sol. There is however this important difference. In the sol the gold originally molecular, condenses around nuclei to form a stable two-phase system, the degree of dispersion of which is determined by the rate of formation of nuclei and by their rate of growth. In a smoke although the process of formation is apparently analogous it results in the production of an unstable system and the primary particles formed by condensation on nuclei of the supersaturated vapour coagulate rapidly so that the degree of dispersion of the system changes continually with lapse of time.

### Coagulation.

This property of continuous and spontaneous coagulation is the most striking characteristic of disperse systems in gases. The smoke particles of whatever substance they are composed stick together when brownian motion brings them in contact. Probably a high percentage of the collisions are effective and although this has not been proved by direct experiment, it has been shown that adherence results from the majority of collisions between smoke particles of different kinds with various surfaces.

By determining how the number of particles in a coagulating smoke diminish with time the course of the process can be followed quantitatively. Numerous smokes have been investigated in this way by different workers but the counting of smoke particles with the slit ultra-microscope presents unexpected difficulties and led originally to erroneous results. Several methods are now available which agree among themselves and the data obtained from these show that the coagulation of very many smokes follows a simple law. If  $n_1$  and  $n_2$  represent the number of particles present per c.c. at times  $t_1$  and  $t_2$  minutes from the formation of the system, then  $1/n_2 - 1/n_1 = K(t_2 - t_1)$  where  $K$  is a constant. Thus if the reciprocal of the number of particles present in a given volume of smoke are plotted against the corresponding times a straight line is obtained.

$1/n$  denotes the average space inhabited by a particle in the smoke at any instant of time. It is termed conveniently the particulate volume and  $n$  the particulate number. Although the validity of this relationship has been questioned there is so much experimental evidence to support it, that we believe it represents the course of coagulation of the majority of smokes to at least a rough approximation.

From this expression it is easy to see that the rate at which the particles disappear by coagulation depends only on the square of the number present and the constant  $K$ , i.e.  $-dn/dt = Kn^2$ . In any given smoke, coagulation will be very fast in the early stages when the number concentration is high and later will fall off rapidly. A comparison of the values of  $K$  obtained experimentally for different smokes in air under normal conditions of temperature and pressure shows no striking variation. Clearly the coagulation process is to some extent independent

of the nature of the particles. The coagulation constant for any one smoke does, however, vary:—

- (a) with the average size of the particle, fine smokes coagulate faster than coarse ones;
- (b) with the size distribution or range of sizes of the particles. When the size range is small the smoke approaches to the homogeneous, and systems of this type coagulate more slowly than ordinary smokes which are as a rule widely heterogeneous;
- (c) with the form and shape of the particles and the aggregates they form.

An ideal or perfect smoke would consist initially of even-sized spherical particles which on coagulation coalesce to form progressively larger spheres. The kinetics of such a system were worked out for some many years ago by Smoluchowski.

The theoretical treatment of smokes along those lines is more complicated because smoke particles lie between size limits which are comparable with the mean free path of the molecules of the gaseous medium. The simple mobility defined by Stokes' law has to be modified by terms, taking account of the discontinuous nature of the surrounding gas.

Smoluchowski's theory thus modified does, however, reproduce quite remarkably the experimental results obtained with smokes approximating to the above ideal conditions, as Patterson and Cawood have shown in their studies of stearic acid smokes.

It can be shown that the theory for a homogeneous smoke leads to an expression similar in form to that found experimentally:  $K$ , the so-called coagulation constant, being given by  $K = \frac{4}{3} \frac{RT}{\eta N} \left( 1 + A \frac{l}{r} \right)$ , where  $R$  = gas constant,  $T$  = absolute temperature,  $N$  = Avogadro's constant,  $\eta$  = the viscosity of the medium,  $l$  = mean free path of the gas molecules,  $r$  the radius of the particle, and  $A$  a constant.

Thus theory leads to the expectation that the particulate volume graph would be curved,  $K$  decreasing as coagulation proceeds. Actually the curvature is so slight for particles of the size found in homogeneous stearic acid smokes of the weight concentration used that it is doubtful whether it would be detected experimentally.

This expression also predicts the influence of pressure and temperature on the rate of coagulation as well as that of the size of particle and the viscosity of the medium. Up to the present the coagulation of smokes in gaseous media other than air has not been studied. Data, too, on the coagulation rate of small particles are scanty and the effects of temperature and pressure have hardly been investigated.

On the theoretical side the applicability of Smoluchowski's theory to ideal aerosols has been much discussed recently. Experimentally a really suitable smoke is difficult to obtain. Up to the present the nearest approximation to a perfect smoke would appear to be the homogeneous and reproducible stearic acid systems mentioned above, though a smoke such as that of paraffin in which the particles are liquid would possibly offer advantages.

Considerable progress has been made in the production of smokes for experimental purposes which approximate to homogeneity. It is clear from the nature of coagulation that a monodisperse system of primary particles can only be obtained by very rapid dilution of the molecularly disperse material.

This can be accomplished by volatilization in a rapid air blast, by chemical reaction at high dilution, or by photochemical decomposition as in the elegant method discovered by Winkel and Jander in which highly diluted iron carbonyl vapour is decomposed by light of short wave length. In all these methods even at the highest dilutions in which the weight concentration of the smoke is only of the order of a few milligrams per cubic metre, the number of particles a few minutes after the smoke is formed is several millions per c.c.

Extrapolation of the particulate volume graphs for this type of smoke shows that initially the number of primary particles must be very great.

A rough calculation from the dilution of a stearic acid smoke gives  $10^{12}$  per c.c. and recently Fuchs and Oschman by diluting with great rapidity a sulphuric acid smoke have actually formed an aerosol consisting of primary particles. They found the number per c.c.  $10^{11}$  and the size about  $10^{-6}$  cms.

In these experimental smokes it is clear that the ultra-microscopic particles counted are aggregates of a large number of primary units and that the coagulation process is far advanced before counting is possible. The primary particles are amicroscopic. The possibility of obtaining stable systems of these is evident and opens up an interesting line of research. Atmospheric nuclei and large ions probably belong to this class. The rapid dilution of chimney smoke in a high wind may well form these systems and they are likely to be present in ordinary smokes in the early stages.

The rapidity of coagulation in systems of high number concentration is evident when the time taken to halve the number of particles is calculated. Using for this purpose the  $K$  value for a stearic acid smoke, viz.:  $0.51 \times 10^{-9}$  cm.<sup>3</sup> sec.<sup>-1</sup> we find for a system of  $10^{11}$  particles per c.c.  $t = 0.02$  sec., for  $5 \times 10^8$  per c.c. 6.6 minutes and for  $10^5$  per c.c. 5.5 hours. To obtain a stable system of primary particles the original smoke must be diluted with  $10^5$  or  $10^6$  volumes of air in a fraction of a second.

So far practically nothing is known about the early stages in the formation of smokes. Probably as in sols, the rate of nuclear formation and velocity of their growth are important stages. Now that it is realised that smokes originate from highly dispersed amicroscopic primaries there is hope that methods of attacking these difficult problems will be developed.

It will be obvious from the foregoing considerations that the experimental smokes so far discussed are special types. Although the particles composing them are aggregates and formed from a large number of primaries they are at least approximately homogeneous. This is evident from their appearance in the field of the ultra-microscope. Unfortunately no satisfactory quantitative studies have been made of the size distribution of particles in smokes. Both from the point of view of the theory of coagulation and also from that of the actual composition of smoke much is to be learnt from such investigations.

The ordinary smoke of factory and domestic chimneys and, indeed, the great majority of industrial and laboratory smokes belong to the heterogeneous type and exhibit a wide range in particle size forming frequently large loosely built aggregates of microscopic dimensions or irregular chains composed of small units. This structure which is characteristic of the particles in concentrated systems especially in

metallic oxide smokes must affect the mobility of the particles and their collision frequencies. Further, as Kohlschütter was the first to show the densities of such particles are very much smaller than that of the material composing them. Whether this structure revealed by the microscope is a replica on a larger scale of the structure of ultra-microscopic particles is an open question. The application of X-ray or electron diffraction methods to the examination of smoke films might here prove of considerable value and interest.

Up to the present no normal aerial systems have been discovered in which coagulation does not take place, and no counterpart to the sol stabilised by protective agents has been observed. Although the suspended particles in gases doubtless adsorb molecules of the medium, this effect appears to have little influence on their adhesion. It is possible that a stabilising action might be detectable in gases which are highly adsorbed by the disperse material. Again whether the particles carry electric charges or are electrically neutral has little affect on the rate of coagulation. It is well known that smoke particles readily catch ions of both signs from the surrounding medium and when formed in a highly ionised atmosphere, such as in the presence of X-rays or by high temperature reactions, are strongly charged, but the smokes contain as a rule equal numbers of  $+$  and  $-$  units and are usually electrically neutral. Highly charged unipolar smokes can, however, be formed and these might be expected to show a diminished rate of coagulation. This has been found by Fuchs to be the case for highly charged unipolar oil smoke, though experimental investigation is difficult on account of the space charge which quickly drives the particles to the walls of the containing vessel. In this investigation it is interesting to note that the splitting up of the complexes into simpler units was claimed to take place during charging.

The rate at which ions are caught by particles of various sizes and the limiting charge acquired in an ionic atmosphere of given intensity are important factors in electrical precipitation and will be discussed in communications to this meeting.

Apart from electrical precipitation which at the moment is probably the most practical way of removing fine particulate matter, a study of disperse systems in gases indicates the possibility of the development of other methods which may in the future have many applications. Theory indicates that the rate of coagulation is determined by the probability of encounter of particles in brownian motion. Any factor then, which will increase the sphere of influence or the mean free path of these smoke particles will hasten coagulation. The production of turbulence in the medium by the formation of eddies and vortices will bring this about to some extent though for fine particles it is not so effective as for larger.

Of great interest is the effect of sonic and supersonic waves in bringing about rapid coagulation. This has been studied both experimentally and theoretically in recent years, notably by Brandt and Hiedemann in Germany, and Andrade in this country, and striking results have been obtained.

The movements of smoke particles in a temperature gradient and the formation of a dust-free space around hot bodies has been known ever since the pioneering work of Aitken and of Lodge in the last century. Precipitation of smoke and dust on cold surfaces is a common phenomenon but the mechanism of the process and the forces involved has

never been satisfactorily explained. Attention has recently been turned to a more detailed study of this effect and it has been utilised on a small experimental scale in the thermal precipitator for determining dust and smoke in disperse systems in gases.

### **Dusts.**

Whilst smokes are formed by condensation, dusts whether natural or artificial are produced invariably by disintegration or dispersion processes. Speaking generally they consist of larger particles which from their mode of origin are denser and composed of much larger units. Hence they sediment more rapidly than smokes. Again the number concentration in dust systems is usually low though on account of the size of the particles they reflect light and show a high optical density. Dusts do, however, coagulate and the large primary units stick together when they come in contact forming complexes, but the process is slow and plays only a secondary part in their life history. Theoretically the coagulation of these systems presents interesting features but it has not so far been studied in any detail. Another characteristic of dusts is the ease with which the particles acquire electric charges, probably produced by frictional effects. In combustible materials such as coal dust this easily leads to dust explosions when the medium is air.

The toxic effects of siliceous dusts in industry are well known, but although much careful work has been done in this field, information on what size ranges of particles are the most harmful is still scanty. Progress in the investigation of dusts, and indeed of all disperse systems in gases, is largely a question of technique. Until recently many methods used were open to criticism, but it is possible now to determine with accuracy the mass concentration, number concentration and size distribution in dusts. The investigations of Green have done much to advance this aspect of the subject.

In this brief survey emphasis has been laid on spontaneous coagulation as a specific characteristic of these systems. It must, however, be pointed out that the very dilute smoke which pollutes the air of cities, as well as the many natural systems included in the terms fog, mist, and haze, change only with extreme slowness on account of the low number concentration of their particles. Nevertheless, coagulation even in these systems may be of significance, especially in the case of atmospheric nuclei and very small particles.

**PART 1 (a). THE GENERAL PROPERTIES OF DISPERSE SYSTEMS COMPOSED OF SOLID AND LIQUID NON-VOLATILE PARTICLES (i.e. SMOKE, DUST, OIL, FOGS, ETC.).**

**ON THE PROPERTIES OF AEROCOLLOID SYSTEMS, WITH REGARD TO THEIR DEPENDENCE ON THE METHODS OF FORMATION.**

BY KARL ERNST STUMPF AND GERHART JANDER.

*Received in German 25th March, 1936, and translated by J. COLVIN.*

Previous investigations have shown that in contrast with liquid sols, aerosols are invariably unstable systems which aggregate and sediment more or less rapidly. Hence the unstable condition of aerosols is only to be compared with the special case of the rapid coagulation of liquid sols.

In the investigation of aerosols, therefore, two important questions arise: (1) what properties do they possess in parallel with liquid sols, and (2) on what factors do the properties of aerocolloid systems depend. This paper will examine principally the problems associated with the second question.

The properties of liquid sols are determined mainly by (1) the nature of the dispersed material, (2) that of the dispersion medium, (3) the effect on the prepared sol of additions which influence the electrical charge of the disperse phase or exercise a protective colloid action, and (4) the method of preparation itself. We shall examine the extent to which the properties of aerocolloid systems are determined by these factors.

The aerosols hitherto investigated show real differences according to the chemical composition of the substance used. Thus mercuric iodide smokes and aerosols of certain dye stuffs<sup>1</sup> age specially rapidly, since the decrease in the number of particles and the increase in their size depend not merely on aggregation, but also on the isothermal distillation or sublimation taking place in these systems. These substances have an appreciable vapour pressure, which increases with increasing curvature of the surface,<sup>2</sup> i.e. with decreasing particle size, so that small particles evaporate more readily than large and the vapour condensing on the larger particles, still further increases their size.

However, in systems where isothermal distillation is absent, because of a vanishingly small vapour pressure, singularly rapid ageing has been observed, as in certain metallic oxide smokes,<sup>3</sup> e.g. ferric oxide smoke.<sup>4</sup> Whytlaw-Gray has shown that these systems aggregate in a special way with formation of chain-like aggregates. The individual particles possess to some extent a dipole nature; they unite preferentially at the surfaces of the individual particle, at which it would grow preferentially as a crystal.

<sup>1</sup> Whytlaw-Gray and Patterson, *Smoke*, London, 1932, 168 ff.

<sup>2</sup> W. Thomson, *Phil. Mag.* (4), 1871, 42, 448.

<sup>3</sup> Whytlaw-Gray, *loc. cit.*, 51, 81 ff.

<sup>4</sup> Jander and Winkel, *Kolloid-Z.*, 1933, 63, 5.

The formation of chain-like aggregates in aerosols also can depend on pyroelectric properties of the disperse phase. According to Beischer,<sup>5</sup> the needle-like crystals of aminoazobenzene, produced by cooling the supersaturated vapour, are charged pyroelectrically in such a way that each end carries an opposite charge. Hence it is understandable that the smoke would aggregate rapidly, forming chains such as Beischer has observed ultramicroscopically. Moreover, even in the absence of isothermal distillation or any special kind of aggregation, the differences arising from the physical properties of the various substances used as aerosols also leads to more or less rapid ageing. The rapid coagulation of unidisperse sols may be described by Smoluchowski's equation in the form,

$$-\frac{dn}{dt} = \frac{2}{3} \cdot \frac{RT}{\eta N} \cdot n^2,$$

where  $-\frac{dn}{dt}$  is the velocity of disappearance of  $n$  particles present at time  $t$ .  $R$  is the gas constant,  $T$  the absolute temperature,  $\eta$  the viscosity of the dispersion medium, and  $N$  the Avogadro number. In this simplified form, the equation holds good provided that the effective radius of the particle is equal to its real radius, i.e. provided that the particles remain attached to one another only at an actual collision. This law, which has been applied by Whytlaw-Gray<sup>6</sup> to aerosols, presupposes spherical particles. This condition is fulfilled only in fogs or in smokes produced by cooling fogs if the solidifying droplet does not change its shape by crystallisation. The stearic acid smoke used by Whytlaw-Gray approximates to this ideal case. All smokes of substances difficult to melt or of readily crystallisable substances vary more or less widely from the above requirements, so that their more or less rapid ageing is understandable.

The properties of aerosols are, therefore, to a great extent dependent on the substance used.

So far as we know, no investigations have been made of the effect of the gaseous dispersion medium on the resulting colloid system. From Smoluchowski's equation, we should expect the viscosity of the medium to affect the coagulation velocity, in the sense that the velocity increases with decreasing viscosity.

Attempts to influence the behaviour of the prepared aerosol by electrification, or by the addition of "protective" substances, clearly show the great difference between liquid sols and aerocolloid systems. This is due to the difference in the dispersion medium, liquid or gas. Both in lyophobic and in lyophilic sols, the dispersion medium plays an important part in stabilising the sol, by making unipolar electrification possible or by adsorption at the surface of the particle. Whytlaw-Gray and his co-workers<sup>7</sup> and others<sup>8</sup> have nowhere indicated any such stabilising action of the dispersion medium on aerosols. At the slight degree of electrification, bipolar or unipolar, which certain methods of preparation produce, no measurable effect on the rate of ageing has been detected. Moreover, with the usual strong unipolar electrification, no stabilisation results. There must be other effects, unknown in liquid sols, which permit the disappearance of aerosols. N. Fuchs has shown recently<sup>9</sup> that strongly

<sup>5</sup> *Z. physik. Chem. A.*, 1936, **176**, 1.

<sup>6</sup> *Loc. cit.*, 57 ff.

<sup>7</sup> G. Jander and A. Winkel,<sup>4</sup> 10 ff.

<sup>8</sup> N. Fuchs and J. Petrijanow, *Acta Physicoch. U.R.S.S.*, 1935, **3**, 827.

<sup>9</sup> *Loc. cit.*, 146 ff.

charged unipolar aerosols do not aggregate, as might be expected, owing to the electrical repulsion between the particles; however, the cloud has a tendency to expand. The particles migrate to the walls of the vessel, to which they give up their charges and remain attached. Stabilisation would be obtained by unipolar electrification only if the walls of the vessel were charged, and of the same sign as the charges on the particles, so that the tendency of the particles to migrate to the walls would be compensated by the repulsion exerted on them by the correspondingly charged walls.

By analogy with liquid sols, stabilisation of aerosols by the action of protective colloids is conceivable, so long as these protective aerosols are stable as pure aerosols, *i.e.* so long as they do not aggregate on undergoing the collisions due to their Brownian motion, but collide elastically. Such aerosols are at present unknown; the majority of collisions between particles lead to aggregation. Aggregation may, however, be retarded by the addition of substances which are adsorbed at the surface of the particles,<sup>10</sup> an effect certainly not due to elastic collisions between the protected particles. Probably the effect is to be ascribed to impedance of factors which accelerate ageing, such as isothermal distillation, or the formation of polar crystalline particles. The stabilising substances so far used (*e.g.* phenol or oleic acid) cannot be added subsequent to formation of the aerosol, but must be evaporated along with the substance forming the sol, so that they condense with it. No experiments (particularly with regard to a possibly expected retardation of the coagulation velocity) have been made with subsequent additions of vapour to be adsorbed as a protective envelope.<sup>11</sup> So far, then, attempts to stabilise aerosols, either by electrification subsequent to preparation, or by the addition of other substances, have achieved no real success.

In contrast with liquid sols, therefore, the properties of a given aerocolloid system are fixed as soon as its preparation is complete. Of the more important methods of preparation, the first comprises the subdivision of a coarser system \* to one of particles of colloidal dimensions. The second method involves producing a colloidal disperse phase by aggregation or coagulation from a molecularly disperse (gaseous) phase. All the usual methods of preparation depend on this condensation process methods. It may be further subdivided into three groups, the physical, chemical and photochemical condensation methods.<sup>12</sup>

In the physical condensation method, the substance to be investigated is heated to produce evaporation of a considerable mass and the disperse colloid phase results by subsequent condensation. In this way, aerosols of a large number of inorganic and organic substances have been prepared.

By chemical condensation methods, two substances in the form of vapour react with the formation of a product, whose vapour pressure at ordinary temperatures is very slight, or practically zero (*e.g.*  $\text{NH}_4\text{Cl}$  smoke from  $\text{HCl}$  and  $\text{NH}_3$ ;  $\text{H}_2\text{SO}_4$  fog from  $\text{SO}_2$  and steam and metallic oxide smokes from zinc ethyl or from base metals evaporated in the arc with atmospheric oxygen).

By the photochemical condensation method, a substance suitably illuminated yields an aerosol product of vanishingly low vapour pressure. So far, only ferric oxide dusts, resulting from the photochemical decomposition of iron pentacarbonyl, have been obtained by this method.<sup>4</sup>

In order to obtain reasonably reproducible results, it was necessary to improve the methods of preparation of aerosols. Using a physical conden-

\* The atomisation of liquids is the outstanding example, and is unimportant since only relatively coarse, rapidly aggregating polydisperse systems are obtained. It is excluded, therefore, from consideration.

<sup>12</sup> V. N. Fuchs, *Über die Bildung von Aerosolen*; *Acta Physicoch.*, U.R.S.S., 1935, 3, 61.

sation method, Whytlaw-Gray<sup>12</sup> succeeded in preparing highly reproducible aerosols, especially of stearic acid, by using a constant weight of the fog-forming substance and carefully maintaining every detail in the preparation unchanged, otherwise aerosols of different behaviour resulted. The substance was heated in a stream of air in an electrically-heated boat, and the vapour-charged air stream was rapidly cooled by dilution with the cold air in the chamber. If the substance was evaporated directly into the chamber and distributed by stirring, the resulting aerosols at once coagulated more rapidly to much coarser systems, a method which is less exact and yields only poorly reproducible aerosols.

With chemical condensation methods also, finely divided, reproducible aerosols cannot be obtained if the gaseous reactants are mixed directly in the chamber. Fuchs and Oschman<sup>14</sup> have, however, prepared very finely divided and highly reproducible fogs from sulphur trioxide and air containing water vapour, by greatly diluting the reactants and allowing them to react after thorough mixing (by the method they describe) before introduction and distribution through the chamber; the system is rapidly diluted to the concentration at which the investigation is carried out, perhaps simultaneously with the completion of condensation and the beginning of coagulation. This method is only suitable, however, for the production of finely divided and very dilute fogs. Whytlaw-Gray has shown that the electric arc as a means of preparing smokes under reproducible conditions is still less suitable.<sup>15</sup> In contrast to those prepared by other methods, aerosols prepared by the arc are mainly charged and of both signs and, moreover, the formation of chain-like aggregates is clearly shown, a property due more to the nature of the metallic oxide than to the method of preparation.

The ferric oxide dusts<sup>4</sup> prepared by the photochemical condensation method are exceptionally finely divided and highly stable sols with extreme reproducibility.

The most finely divided and most stable systems (and the most reproducible) result by using methods in which the condensation proceeds under the most uniform conditions, and the freshly formed very finely divided aerosol can be equally rapidly and uniformly distributed through the chamber; they age more slowly than aerosols prepared in other ways. According to Müller's theoretical treatment of hydrosols,<sup>16</sup> polydisperse systems coagulate more rapidly than unidisperse systems of the same concentration and particulate number. Approximation to complete unidispersity can only be realised in the very earliest stages, since with the onset of aggregation the condition of uniformity is immediately destroyed. For all quantitative investigations, therefore, it is simpler to use systems which are as unidisperse as possible.

To obtain reproducible, unidisperse systems, special attention must be paid to the conditions under which condensation and coagulation up to the time of uniform distribution in the chamber take place. Our knowledge of the course of these two important processes is slight. Scarcely any work has been carried out apart from investigations on water fogs,<sup>17</sup> on the rôle played in condensation by condensation centres and foreign nuclei. According to Whytlaw-Gray's views,<sup>18</sup> for substances of very low vapour pressure, like stearic acid and arsenic, so high a degree of supersaturation will be produced that the molecules of the vapour itself become effective centres for condensation, so that no foreign nuclei need to be assumed. This will only be the case, however, if the cooling and consequent

<sup>12</sup> *Loc. cit.*, 44.

<sup>14</sup> *Acta Physicoch.*, U.R.S.S., 1935, 3, 65.

<sup>15</sup> *Loc. cit.*, 76, 77.

<sup>16</sup> Wiegner and Tuorila, *Koll-Zeitschr.*, 1926, 38, 3.

<sup>17</sup> See Freundlich, *Kapillarchemie*, 4 Aufl., 1932, 2 Bd. 780 ff.

<sup>18</sup> *Loc. cit.*, 74 ff.

high supersaturation are accomplished rapidly. Now, the cooling of the vapour takes time, and proceeds through all stages from saturated vapour to a state of high supersaturation. At the beginning of condensation, the larger foreign nuclei will act as centres at which larger aerosol particles will be formed. In time, greater supersaturation will ensue, and in addition to the larger particles already present, smaller particles will be formed with the molecules of the substance itself acting as condensation centres. Thus the kind of cooling (*Abschreckung*) will exercise a profound influence on the nature of the aerosol. The faster the cooling, the faster will the critical region (in which larger particles are formed at foreign nuclei) be passed through, leading to a correspondingly more finely divided and uniform aerosol. In the chemical and photochemical condensation methods, the "chilling" is instantaneous, and hence the magnitude of the supersaturation depends on the speed of the reaction.

Moreover, even in respect of the coagulation which occurs prior to distribution in the chamber, rapid cooling of the condensing vapour is valuable. From Smoluchowski's equation describing the course of coagulation given above we may deduce the effect of temperature, viscosity of the medium and particle concentration on the rate of coagulation. The higher the temperature and the higher the particle concentration, the more rapidly will the aerosol age. If, therefore, cooling is effected slowly, aggregation to coarser particles will proceed proportionately rapidly. The original concentration of the vapour to be condensed similarly influences the aerosol produced; the higher the vapour concentration, the higher the concentration of the resulting aerosol, and the more rapidly will it aggregate. This explains why direct evaporation in the chamber and distribution of the vapour by mere stirring results in coarse heterogeneous systems. In this case, the density of vapour is high at the start, the cooling is in no way uniform and relatively very slow, whereas, if the substance is heated in a tube and blown into the chamber, the vapour and the aerosol concentrations are low, so that by the more rapid and more uniform cooling, a more unidisperse system is distributed through the chamber by the stirring apparatus. Reproducible results can, therefore, be obtained by accurate control of the temperature of heating, velocity of the air stream and rate of stirring in the chamber. Reproducibility is also related to the amount of substance dispersed as fog, in that at the same temperature, a correspondingly longer time is required for the evaporation of a larger amount of material. As a result, whilst the last portions of the substance are evaporated, the earlier portions are already distributed throughout the chamber as aerosol to which the small primary particles rapidly unite with particles which are already aggregated. This explains why arsenic dusts prepared under the same conditions showed different behaviour according to the concentration.<sup>19</sup>

Fig. 1, taken from the paper cited, shows that the more concentrated systems are actually more polydisperse than the more dilute systems. Owing to the longer time needed for the preparation, the final portion evaporated, condenses and aggregates on the particles first formed. By the rapid sedimentation of the large particles thus formed, the average weight of the particle at first quickly falls, until a finely divided and homogeneous system remains; it then begins to rise as expected, owing to coagulation. Since the more dilute systems, owing to their shorter time of preparation, are already uniform, the change of particle weight with time is as expected from the start.

In addition to the condensation and initial coagulation at greater concentrations, the method of distribution in the chamber is of importance in securing uniformity in the resulting system, otherwise imperfect results are obtained. Even when the formation of the aerosol is practically complete before its entry into the chamber, uniform distribution, to which

<sup>19</sup> G. Jander and A. Winkel, *Kolloid-Z.*, 1933, 65, 290.

stirring contributes, opposes homogeneity in the particle size, despite the most careful experimental conditions. This can be roughly confirmed by first distributing the vapour uniformly in the experimental vessel and then effecting sudden condensation, either by cooling or by adiabatic expansion. Condensation invariably occurs partly in the concentrated vapour and partly only during the final distribution in the chamber. Thus, aggregation occurs at different concentrations until uniform distribution has been secured, so that it is never possible to achieve more than approximate homogeneity and reproducibility.

The same state of affairs arises with the chemical condensation methods. If the reactants are first mixed in the chamber, a heterogeneous, rapidly coagulating aerosol results. It is only when the reaction is practically completed before the mixture enters the chamber under constant conditions that highly reproducible fogs are obtained, as Fuchs<sup>14</sup> has shown.

The degree of uniformity secured by the methods so far used depends on the extent to which it is possible to direct and influence reproducibly, the condensation process and the coagulation occurring in the short time prior to entry into the chamber. This cannot be done rigorously, since

FIG. 1.

the two processes follow one another with differences of time and place. The systems thus result from a complex procedure, and must themselves be more or less complex in nature.

We believe that the photochemical method of preparing ferric oxide smokes, should, at least in principle, avoid some of the complications arising in the previous methods. For example, the iron pentacarbonyl from which the aerosol is generated, may be uniformly distributed through the vessel as a vapour. With uniform and intense irradiation by ultra violet light, the formation of the aerosol may be accomplished uniformly throughout the entire volume, and hence the circumstances of condensation and coagulation are everywhere the same. The stirring, essential in other methods to obtain uniformity of distribution, must accelerate coagulation, and is practically dispensed with in this method. We are therefore able with certainty to produce as uniform an aerosol as possible. With sufficiently powerful illumination, strictly comparable aerosols of different concentrations can be prepared. Whilst arsenic dusts prepared thermally and under the same conditions deviated widely from one another in behaviour, according to their concentration, Fig. 2 shows that ferric oxide smokes of different concentration are not so differentiated; the decrease in concentration and in number of particles are always in the same sense.

The two series of experiments cannot be strictly compared unrestrictedly, because of the different ranges of concentration. The smaller initial average weight of particle in the ferric oxide smokes, in comparison with that of the arsenic smokes, is characteristic of a highly undisperse aerosol.

Whytlaw-Gray<sup>20</sup> has shown that ferric oxide smokes are not, unfortunately, suitable for general investigations, as they aggregate in a special way. Moreover, the course of the reaction expressed by the equation

is completely unknown, so that unforeseen complications may arise here.

FIG. 2.

### Summary.

The behaviour of an aerosol will be decisively affected by the chemical and physical conditions prevailing during preparation, particularly in regard to the form and size of the particles formed. Relatively finely divided and approximately undisperse systems have been obtained in different and reproducible ways, in all of which, however, there are some imperfections, which have been discussed. No method of preparation, ideal in every respect, has so far been evolved. Further improvement in methods of preparation depending on a closer knowledge of the rapidly occurring process of condensation preceding the formation of particles of colloidal dimensions, seems to us important, if we are to penetrate further into the characteristics of aerosols.

<sup>20</sup> Whytlaw-Gray, *J. Chem. Soc.*, 1935, 276.

### GENERAL DISCUSSION.

**Dr. N. Fuchs (Moscow) (communicated):** In the work of Urasovski and Kusmenko,<sup>1</sup> the dispersity of  $\text{NH}_4\text{Cl}$  smokes formed by volatilisation in different media was compared, the number of particles per c.c. in 30-minute old smokes being

Medium.	Air.	Methane.	Methyl Alcohol.	Ethyl Alcohol.	Propyl Alcohol.	Benzene.
Number of particles per c.cm.	$1.0 \times 10^6$	$1.5 \times 10^6$	$2.5 \times 10^6$	$3.0 \times 10^6$	$0.5 \times 10^7$	$0.8 \times 10^7$

<sup>1</sup> Urasovski and Kusmenko, *J. Physic. Chem. (Russian)*, 1935, 6, 896.

As the weight concentration of smokes was very large (2 grams per cubic meter) they must have been very highly coagulated by the time they were examined and the results obtained can be interpreted as due chiefly to the different rate of coagulation in these media. The above figures show a complete parallelism with the diffusion coefficients of the media.

The same authors studied also the effect on the dispersity of smokes caused by the small admixture of some easily adsorbed vapours to the air in which they are formed. Only highly coagulated smokes were again examined. The most striking effect was observed with the admixture of phenol vapours, which markedly increased the dispersity of some smokes ( $\text{NH}_4\text{Cl}$ ) and decreased that of others ( $\text{MgO}$ ). We agree completely with Stumpf and Jander that this effect should not be attributed to the change in the effectiveness of collisions between the particles caused by the adsorbed layer. Most likely this layer causes a change in the size and form of the primary crystals,\* and consequently in the structure of the aggregates formed from them. It would be very desirable to repeat these experiments, but adding the phenol vapours not before but after the formation of the smoke, as Stumpf and Jander have quite justly remarked.

The charging of the walls of the smoke-chamber (p. 1050) will not lead to any stabilisation of an unipolarly charged smoke. If all the walls are charged to the same potential there will be no field whatsoever inside the chamber. If the potential is different—the particles will move across the chamber and settle on one of its walls.

## A SEDIMENTATION METHOD OF FINDING THE NUMBER OF PARTICLES IN SMOKES.

BY R. WHYTLAW-GRAY, W. CAWOOD AND H. S. PATTERSON.

*Received 10th February, 1936.*

The interpretation of the process of coagulation in smokes which has been previously put forward<sup>1</sup> depends upon the accuracy of counting in an ultramicroscope cell. We have shown that the Zsigmondy slit ultramicroscope gives an entirely erroneous estimate of the number of particles, and in consequence a special type of cell which we believe enables accurate data to be obtained was developed and used.<sup>2</sup> The unreliability of the slit ultramicroscope was first revealed by preliminary experiments on the sedimentation of smokes. This sedimentation method has been perfected and since it is free from certain objections which might be urged against counting with the special cell, the agreement which we have found serves to conform the validity of the previous conclusions on smoke coagulation.

Essentially the method consists in enclosing a known volume of smoke taken from the centre of the experimental smoke chamber between two strips of optically worked glass which form the top and bottom of a shallow box. The particles settle mainly on the lower plate and the number of particles can be counted when the deposit is suitably illuminated. Knowing the depth of the box and the area in which the count is made, it is easy to calculate the number of particles per c.c. of the smoke.

<sup>1</sup> Patterson and Cawood, *Proc. Roy. Soc.*, 1932, 136A, 538.

<sup>2</sup> Nonhebel, Colvin, Patterson and Whytlaw-Gray, *Proc. Roy. Soc.*, 1927 116A, 540; Patterson, Whytlaw-Gray and Cawood, *ibid.*, 1929, 124A, 502.

### Sedimentation Method of Counting.

The enclosing of a known volume of smoke was accomplished by means of the device shown in Fig. 1.

The two glass plates A and B slide along the surface of a brass plate C perforated with a hole G. The glass plates are kept in position by fitting in grooves D, and are raised slightly above the level of the brass plate by strips of paper gummed to their edges. This device prevents abrasion of the highly polished surfaces by the brass. To the top of the plates are gummed strips of thin velvet ribbon to ensure that the plates fit tightly and move smoothly in the grooves. The plates originally occupy the position EF and are pulled simultaneously over the aperture into the position HK by means of strings. The small volume of smoke present in G is thus enclosed between the two glass plates and in standing sediments almost entirely on to the lower. The plates used are about

FIG. 1.

9 cm. long by 3 cm. wide with a bevel at the front end whilst the aperture G is oval, the size being about 1.2 cm. by 2.5 cm. Owing to slight turbulence and to diffusion, the deposit is apt to be irregular near the edges and it is therefore necessary that the area of G shall be large. In practice, however, the greater part of the deposit is perfectly uniform provided that the cell is not too deep. Actually, we have used cells varying in depth from 2 to 10 mm. and within these limits the deposit is quite satisfactory though it is more uniform the shallower the hole. The brass holder carrying the plates was designedly of heavy metal to ensure thermal equilibrium and the absence of convection in the smoke during settling. We have termed the glass plates collector slides, and the brass cases in which they slide, collector slide holders.

After the deposit had settled, the slides were removed from the holder and examined microscopically, using a 16 mm. apochromatic objective N.A. 0.30 and a ( $\times 12$ ) or ( $\times 20$ ) eyepiece carrying a suitable squared graticule. The surface of the slide on which the particles had sedimented was illuminated from the front by a powerful focused beam of oblique light. The particles thus appeared as small bright diffraction discs on a black background. These operations were always carried out in a dust-proof box containing the microscope and slides, to avoid errors due to the deposition of floating impurities in the air. Counting presented no difficulty, the average number of particles per square of the eyepiece being obtained by enumerating a large number of fields in different parts of the deposit. Knowing the number of particles per square, the area of slide corresponding to the square, and the depth of the slide, the number of particles per c.c. can easily be found.

In the intense beam of illumination used the ordinary surface of glass even when optically polished shows numerous imperfections which simulate particles. By special polishing however, these can be almost entirely eliminated. In addition it is necessary that the surfaces before use shall be carefully cleaned. With certain types of glass this cleaning is not very difficult when the technique has been acquired and the surface when cleaned remains free from imperfections over long periods. With other

types of glass it appears practically impossible to rid the surface, even for short periods, of particulate matter. Thus on one hand the gentle friction of cleaning may produce such electrification of the surface that any particulate matter in the vicinity descends on the slides like a snow-storm, whilst on the other, particulate films due probably to moisture, may be almost impossible to eliminate or may be formed on standing for a short period. We wish to express our indebtedness to Sir Herbert Jackson, K.B.E., F.R.S., for kindly advising us as to the best types of glass to use, and also to Messrs. Hilger, Messrs Taylor, Taylor and Hobson, and Messrs. Cooke, Troughton and Sims, for obtaining the very special surfaces necessary. Even under the best conditions, however, the cleaning of the slides calls for considerable skill. In all cases when the slides had been cleaned, they were examined before use in the manner described to ensure that they were free from deposits. Also after they had been exposed to a particulate cloud, the unexposed portion was scrutinised to see that the surface had not deteriorated. We found that the cleaning was best effected by a fine lawn cloth which had been treated beforehand with hot sodium carbonate solution and washed in pure water. The slightest trace of grease spoilt the surface immediately.

In studying the coagulation of a smoke, six or more of these collector slides were fixed to a suitable support in the centre of the smoke chamber and the slides were drawn at definite times by means of strings passing through corks in the side of the chamber.

### Experimental Results for Coagulation.

This method has been applied to a large number of smokes and a considerable mass of data accumulated. A few typical results giving the

variation of number and particulate volume with time are given in Table I. The corresponding particulate volume-time curves are shown in Fig. 2.

It is evident that these coagulation curves are entirely analogous to those obtained with the special ultramicroscope cell. Actually a number of comparisons of two methods of counting have been made simultaneously on the same smoke. For this purpose, cadmium oxide smoke from a cadmium arc was used. The data obtained in two different experiments are given in Table II., whilst Fig. 3 shows the corresponding particulate volume-time curves.

It will be seen that there is a close agreement between the two sets of results. This is, perhaps, the more striking when it is considered that

the two methods are subject to entirely different errors. It may be remarked that the examples given are those for smokes of a heterogeneous type which exhibit a large variability in the coagulation rates.

Counting by sedimentation has, however, its limitations. It is essential that the material used shall not be hygroscopic and obviously liquid particles which tend to wet the glass cannot be counted after settling on a slide. We have often watched the settling of tobacco smoke, of which a number of the particles are liquid, on a glass surface and it is interesting to see how rapidly the majority of the particles either disappear or diminish greatly in brightness when they come into contact with the glass. Further with a highly dis-

perse smoke, especially in its early stages, all the particles may not be enumerated on account of the low intensity of the light scattered by the smaller units. In addition, a time correction of small but uncertain magnitude should be applied to these early points to allow for the coagulation taking place during sedimentation. Consequently, the collector slide counts for very fine smokes will be too low.

### GENERAL DISCUSSION.

**Dr. R. Lessing** (*London*) asked whether the method was also applicable to dusts.

**Professor F. G. Donnan** (*London*) drew attention to the fact that the first observations on photochemically produced disperse systems in gases were made by Tyndall very many years ago. In fact, the famous "Tyndall beam" arose from this work.

**Dr. F. T. Peirce** (*Manchester*) said: The question seems to be whether there is real physical meaning in the zero of time on the coagulation curve. Is the extrapolation to zero made along the linear empirical relation of  $1/n - t$ , or in accordance with the theoretical expression for  $K$ ?

**Dr. W. Cawood** (*Leeds*), in reply, said: The method would be easily applicable to dusts of the size range down to the limits given. We have successfully obtained a thick deposit with dusts of low concentration, by using collected slides of greater depth than those described. This method is, of course, quite different from the ordinary method of sedimentation on to a cover glass, where the glass surfaces are not sufficiently perfect for oblique illumination to be used and with direct light the smallest particles are not counted.

FIG. 3.

## THE INFLUENCE OF PRESSURE ON THE COAGULATION OF FERRIC OXIDE SMOKES.

BY W. CAWOOD AND R. WHYTLAW-GRAY.

Jander and Winkel,<sup>1</sup> in a comprehensive research on ferric oxide aerosols, have shown that perfectly reproducible smokes can be obtained by the photochemical decomposition of dilute iron carbonyl vapour ( $\text{Fe}(\text{CO})_5$ ) in air. They point out that these ferric oxide smokes exhibit, in their early stages at least, a high degree of homogeneity and that the

<sup>1</sup> *Kolloid Z.*, 1933, 63, 5.

method provides a ready means of studying the coagulation of aerosols at varying pressures.

The results, however, which they obtained for the course of coagulation at atmospheric pressure differ markedly from those of the majority of smokes we have examined and we attribute this difference to the method employed for counting the number of particles. Moreover, the experiments they carried out at pressures below atmospheric, though showing clearly that coagulation takes place at a greater rate, did not give any indication of the form of the coagulation curves. For these reasons a further study has been made of the ferric oxide aerosols which are formed by the very elegant method of photochemical decomposition discovered by these two investigators.

### Experimental.

In any research on the coagulation of smokes the essential measurement is the determination of the change with time of the number of particles per unit volume. For this purpose counting with the Zsigmondy slit ultramicroscope is often used, but this method, as we have shown, is unreliable when applied to smokes and may frequently lead to erroneous results.<sup>2</sup> In the experiments to be described we have therefore used the improved form of counting cell and the method which experience has shown to be reliable.<sup>3</sup>

Our arrangements have been criticised by Jander and Winkel<sup>4</sup> but we wish to point out that our method has been tested by comparison with two other independent methods of counting, *viz.*: the modified Aitken method developed by Green<sup>5</sup> and a sedimentation method described in this discussion. All three methods agree closely. We believe, therefore, that our system of counting particles is reliable.

The smokes were dispersed in a similar manner to that used by Jander and Winkel.<sup>1</sup> A thin glass capsule containing a solution of iron carbonyl dissolved in anhydrous ether was broken by means of an electromagnetic arrangement, at the centre of a 20 litre pyrex globe containing filtered air. The flask was radiated by placing it upon a rotating table between two 10 ampere arcs for six minutes. It was then connected with the counting cell and observations were made at suitable intervals of time.

The first experiments were carried out at atmospheric pressure, in order to test the reproducibility of the smokes. Three smokes of equal weight concentrations (16.5 mgms.  $\text{Fe}_2\text{O}_3$  per cubic metre) were counted. When the results were plotted in the usual manner of particulate volume against time, straight lines were obtained in each case, within the limits of experimental error. Plotted in this manner each graph extrapolated back to near the origin and the slopes of the three agreed closely, the

following values for the coagulation constant  $K$  in the equation  $\frac{1}{n} - \frac{1}{n_0} = Kt$  being obtained.

Concentration.			$K$ . (cm. <sup>3</sup> /min. $\times 10^3$ ).

2.	"	" "	0.407
3.	"	" "	0.399

The experimental points of one of the smokes are reproduced in Fig. 1. These results show that the smokes are highly reproducible, and that

<sup>2</sup> *Proc. Roy. Soc.*, A1927, 116, 540.

<sup>3</sup> Patterson, Whytlaw-Gray and Cawood, *Proc. Roy. Soc.*, A1929, 124, 502.

<sup>5</sup> *Phil. Mag.*, 1927, 4, 1046.

the coagulation curves are very similar to those which we have obtained previously. They do not, however, agree with Jander and Winkel's graphs for smokes of a similar concentration, which exhibit a distinct curvature and show a much higher number concentration at corresponding times. It may be noted that earlier counts made by one of us with a Zsigmondy slit ultra-microscope and known to be erroneous, approximate closely to their results.\*

Coagulation curves at pressures below atmospheric were obtained in the following way. After filling the 20 litre globe with filtered air and introducing the thin glass capsule containing the ethereal solution of iron carbonyl of the standard concentration, the pressure was reduced to a suitable value. The capsule was then broken and the flask radiated. Coagulation was allowed to proceed for a definite period and then filtered air was admitted until atmospheric pressure was reached. The smoke was then thoroughly mixed and counts taken in the usual manner over a period of about half an hour. The extrapolation of the graph so obtained back to the time when the air was admitted gave the number of particles per c.c. to which the smoke had coagulated at the reduced pressure. This procedure was carried out a number of times at the same initial pressure, allowing different

FIG. 1.

FIG. 2.

intervals to elapse before the pressure in the flask was brought up to atmospheric. In this way a number of points was obtained on the coagulation curve at the low pressure. The accuracy of this method

\* *Proc. Roy. Soc., A* 1922, 102, 601

depends upon the degree of reproducibility of the smokes, but the data obtained from different experiments were perfectly consistent and showed no indication of irregularity. The method will be clear from Fig. 2. Thus the lines A, B and C represent the experimental graphs obtained after letting air into the globe. These all proved to be straight lines

FIG. 3.

parallel to the coagulation graph at atmospheric pressure.  $A^1$ ,  $B^1$  and  $C^1$  are the points obtained by extrapolating the experimental graphs back to the time when the pressure in the flask was brought to atmospheric. It may be noted that there is very little error in this as the extrapolation is only of the order of two or three minutes. The points  $A^1$ ,  $B^1$ , and  $C^1$  were then plotted as in Fig. 3, showing the course of the coagulation at the lower pressure. The actual points plotted in Figs. 2 and 3 correspond to the results taken at 400 mm. pressure. The graph at 200 mm. pressure was obtained in a precisely similar manner. In Fig. 4 are reproduced the coagulation curves at 760 mm., 400 mm. and 200 mm. pressure.

These experimental graphs show several interesting features. They confirm Jander and Winkel's observations that the rate of coagulation increases markedly as the gas pressure falls. On the other hand, the relationship between the number of particles present after the same interval of time in systems coagulating at different pressures does not, as these observers affirm, appear to vary linearly with pressure.

The graphs, over the time range considered, are straight and when extrapolated to zero time do not start from the same point. This would indicate that at the lower pressure a smaller number of particles is formed initially than at the higher pressures. With stearic acid it has been shown<sup>3</sup> that in air at normal pressure the number of primary particles must be very large and of the order of  $10^{13}$  per c.c. This value is in approximate agreement with a direct experimental determination made by Fuchs and Oschman,<sup>7</sup> in which they found the initial number per c.c. about  $10^{11}$  and the radius 1.2 to 1.5  $10^{-6}$  cm. in a sulphuric acid aerosol at atmospheric pressure.

Our graphs for  $Fe_2O_3$  at atmospheric pressure also indicate a very

FIG. 4.

Our graphs for  $Fe_2O_3$  at atmospheric pressure also indicate a very

<sup>7</sup> *Acta. Physica chimica U.R.S.S.*, 1935, III, 61.

high initial number and consequently a small value for the radius of the primary particle, whilst those for the 200 mm. pressure show that coagulation must start from much larger units.

Although little is known directly about the early stages of smoke formation it is probable that nuclei are first formed in the supersaturated vapour and that a proportion of these grow rapidly by condensation to primary particles. On this view the results we have obtained indicate either that the number of nuclei present in the initial stages changes rapidly with pressure, or that the number of nuclei is constant but the proportion developing into primary particles becomes smaller as the air pressure falls. The particles in the  $\text{Fe}_2\text{O}_3$  smokes formed at atmospheric pressure should hence consist of aggregates of amicroscopic or ultra-microscopic primaries whilst those formed at low pressures should be composed of markedly coarser units.

To test this point a microscopic examination was made of the deposits obtained from two ferric oxide smokes of the same weight concentration, one of which had been formed and allowed to coagulate for three hours at atmospheric and the other at a pressure of 200 mm. The deposits were obtained both by direct sedimentation on to microscope cover slips and by thermal precipitation. They were examined with a 2 mm. Leitz apochromatic oil immersion objective and illuminated by transmitted light of short wave-length. A marked difference in the character of the units composing the aggregates was at once apparent. In both cases chain-like complexes were predominant but the units in those formed at the higher pressure were beyond the limit of microscopic resolution and were indeed extraordinarily difficult to observe at all, whilst those in the aggregates formed at the lower pressure were very distinctly larger and easily observable.

This result confirms in an entirely satisfactory manner the explanation given of the different starting-points of the graphs in Fig. 4. The effect of gas pressure on the size of the particles is also supported by results obtained by Kohlschutter with smokes of metallic oxides dispersed from an arc in air at various pressures.<sup>6</sup>

The general form of the three graphs and their theoretical significance now calls for some discussion.

### Discussion.

It has been shown that the coagulation of various types of smoke is in conformity with the theoretical expression of Smoluchowski, if certain modifications are inserted to take account of the heterogeneity and the mobility of the smoke particles.<sup>3</sup> Thus the coagulation of a smoke containing about equal numbers of particles of range of radius of about 1 to 7 is given by

$$-\frac{dn}{dt} = \frac{4RT}{3\eta N} \left(1 + \frac{Al}{r}\right) \times 1.25, \quad \text{where } n = \text{number of particles per c.c.,}$$

$n_0 = \text{initial number of particles per c.c.,}$

$l = \text{mean free path,}$

$r = \text{radii of particles,}$

$\eta = \text{viscosity of gas.}$

and consequently

$$t = \frac{\sigma - \sigma_0}{\frac{4RT}{3\eta N} \left(1 + \frac{Al}{r}\right) 1.25} \quad \sigma = \frac{1}{n},$$

$$\sigma_0 = \frac{1}{n_0}.$$

<sup>6</sup> Kohlschutter and Ehlers, *Z. Electrochemie*, 1912, 18, 373.

The factor 1.25 is the heterogeneity factor and has this value for the particular size range mentioned above. Since  $r$  is the average value of the radius it will obviously depend upon the age of the smoke and may be calculated as follows.

If the size range is 1 to 7

$$\text{then } \frac{n}{7} \cdot \frac{4}{3} \pi \rho (x^3 + (2x)^3 + \dots + (7x)^3) = M \times 10^{-9}$$

where  $n$  is the number of particles per c.c.,  $\rho$  their density,  $x$  the radii of the smallest and  $M$  the concentration of the cloud in mgms. per cubic metre.

Therefore the average radius  $r$  of the particles will be

$$r = 4x = 4 \sqrt[4]{\frac{M \cdot 10^{-9}}{\frac{4}{3} \pi \rho \cdot 1.25 \cdot n}}$$

It is interesting to note that the average radius calculated in this way is only about 0.81 of that calculated by assuming that all the particles are of equal radii.

The above expression has been applied to our smokes and the dotted lines in Fig. 4 give the theoretical curves so calculated. The only effect of the reduction of the pressure upon the equation is to increase the value of  $l$ , the mean free path of the gas.

It will be seen that the theoretical curve calculated for the smokes at atmospheric pressure is in good agreement with the experimental curve. The agreement, however, is not at all good at the lower pressures. This is due to the fact that the rate of coagulation of any two particles of radii  $r_1$  and  $r_2$  is proportional to the factor  $\left[ \left( 1 + \frac{Al}{r_1} \right) + \left( 1 + \frac{Al}{r_2} \right) \right]$

The change of this term with pressure is not constant for different values of  $r_1$  and  $r_2$ , consequently the size distribution and heterogeneity of the smokes must alter quite appreciably with change of pressure, even though the mass concentration is kept constant. Thus we should not expect the equation which agrees with results taken at atmospheric pressure to agree with those at reduced pressure unless allowance can be made for the alteration in size distribution.

It must be borne in mind when considering these ferric oxide aerosols that on account of the chain-like character of the aggregates in the later stages of coagulation, the particles even in the earlier stages may deviate considerably from the spherical in form, and the applicability of the Smoluchowski theory modified in the above manner to these may well be questioned. We are led, therefore, to the conclusion that though this theory provides a useful qualitative hypothesis for the explanation of the kinetics of the coagulation of aerosols in general, it cannot be expected to express quantitatively the coagulations of more complex systems such as these ferric oxide smokes, although for certain systems, such as stearic acid, the correspondence between experiment and theory is very close.

### Summary.

A study has been made of the coagulation of ferric oxide aerosols dispersed by the photochemical decomposition of iron carbonyl in presence of air at pressures of 760, 400, and 200 mm. The particulate volume

graphs are found to be linear but their slope becomes steeper as the pressure falls.

The values of  $\sigma_0$  differ markedly in the three cases and indicate that the smokes formed at lower pressures start from larger primary particles.

Microscopic examination of the aggregates confirms this conclusion. The limitations of Smoluchowski's theory when applied to smokes of this type are discussed.

### GENERAL DISCUSSION.

**Mr. C. H. Bosanquet** (*Billingham*) said: The fact that the straight lines showing  $1/n$  in terms of  $t$  at different pressures do not cut the axis of zero time at the same point may be due to the  $l/r$  term in Smoluchowski's equation being predominant in the initial stages when  $r$  is very small. This would cause pronounced curvature of the lines near the origin, the effect being more marked at the lower pressures. Comparison of the values of  $n$  after equal lapses of time would not then give directly comparable results, accounting at least in part, for different mean particle sizes being found.

**Dr. W. Cawood** (*Leeds*) said in reply: If the theoretical curves shown by the dotted lines in Fig. 4 are calculated by assuming  $\sigma_0 = 0$ , then the  $l/r$  correction will not give the required curvature. In practice the curves for the low pressure results, calculated with this assumption are more or less parallel to those given in Fig. 4, but start from zero. The only way to obtain an even approximate agreement between theory and experiment seems to be to assume the initial number obtained by a linear extrapolation of the experimental results.

The effect of the  $l/r$  correction may be shown approximately by solving the equation given in the paper for  $\sigma_0$ .

$$\text{Thus} \quad \sigma_0 = t \cdot \frac{4}{3} \frac{RT}{\eta N} \left( 1 + \frac{Al}{r} \right) - \sigma$$

assuming the experimental values for  $\sigma$  and  $t$ . Since at the low pressures the experimental points do not lie exactly along the theoretical curve, the values for  $\sigma_0$  will not be the same for the different experimental values of  $\sigma$  and  $t$ , but the values of  $\sigma_0$  so obtained are not widely different from those obtained by a linear extrapolation.

The empirical correction for radius in Harper's theory certainly tends to make the curvature smaller, but this correction, which incidentally appears to be given more rigidly by Fuch's treatment of Smoluchowski's equation only applies to particles smaller than about  $3.5 \times 10^{-8}$  cms. radius. In our clouds the particles are larger than this after two or three minutes and consequently the extrapolation would not be greatly changed.

**Dr. W. R. Harper** (*Bristol*) said: The extrapolation of the particulate volume/time graph as a straight line to zero time is inconsistent with the variation of the coagulation coefficient for small particle size implied by the formula assumed in the paper, and though the variation is less on my own theory, it would still be sufficient to invalidate any conclusions concerning the existence of primary particles drawn from this extrapolation.

**Mr. A. G. Grant** (*Darlington*) said: In the formation of a particle of, say,  $10^4$  molecules from a condensing vapour, there must first be a union of two or more molecules, this first group growing until it reached the size of Whytlaw Gray's "primary particle." Although considerations of coagulation apply to these "primary particles," further extrapolation of the curves showing particles size against time, should lead to a bi-molecular particle, unless there is some discontinuity. In other words, either the "primary particle" is a somewhat arbitrary unit, or it represents a point of discontinuity.

**Dr. R. Lessing** (*London*) suggested that the differences observed at varying pressure may be due to the chemical mechanism of the decomposition of iron carbonyl rather than to the behaviour of its vapour. In

the commercial production of nickel from its carbonyl slight variations in the temperature of decomposition changed the structure of the fresh metal bloom deposited on the old nickel pellets. Dewar<sup>1</sup> has shown the influence of pressure on the temperature of decomposition of nickel carbonyl.

Mr. C. F. Goodeve (*London*) said: What is the exact meaning of the term "primary particle," as used in this paper and the introductory paper. The term seems to imply some clearly defined intermediate state between the original molecular dispersion and the colloidal one obeying a bi-molecular coagulation law. The extrapolation to zero time does not seem to be very useful, because it depends on a too accurate measurement of time and definition of the starting-point.

It is necessary also to consider the mechanism of the formation of ferric oxide smokes. The question as to the necessity for condensation nuclei before the formation of smokes or fogs has often been discussed. I am attempting to build up a quantitative theory based on initial clustering of the molecules in a supersaturated gas—a theory somewhat on the lines suggested by Volmer.<sup>2</sup> It is now possible to determine approximately the heat of formation of clusters of 2, 3, 4, etc., molecules, knowing only the latent heat of evaporation of one molecule from a flat surface of the solid or liquid substance. As a rough approximation, the energy required to separate two molecules in contact in a cluster, is one-tenth of that required to remove one molecule from a flat surface. The energy required to remove one molecule from a triple cluster is about twice this and, from a quadruple cluster, less than three times. The latent heat of evaporation of ferric oxide from a crystal is probably not known, but would be greater than 100,000 Cals. per gram molecule. This means that, if two ferric oxide molecules collide and are relieved of their excess energy by radiation or by collision with gas molecules, they would require about 10,000 Cals. per gram molecule energy to break them apart. This amount of energy could rarely be obtained at room temperature, where the average energy per degree of freedom would be a few hundred Calories. Double clusters, once formed, would grow very rapidly to larger clusters and eventually to smoke particles. It is seen therefore, that, in the case of ferric oxide, it is entirely unnecessary to have nuclei present before condensation could occur.

These considerations, however, do not apply to super-saturated water vapour. Two-molecule clusters are held together by only about 1000 Cals. and would be very readily broken up on collision with gas molecules.

From these considerations it is very difficult to see how, with ferric oxide, any discontinuity in the condensation process could occur. The building up of clusters and their coagulation to larger particles would be a smooth continuous process, following approximately the considerations given.

Mr. G. W. Slack (*Leeds*) said: The number of *primary particles* is dependent upon the rate of formation of nuclei and upon their rate of growth when formed. The former (in the case of smokes of  $\text{Fe}_2\text{O}_3$  and similar substances of vanishingly low vapour pressure) is probably equal to the number of molecular collisions and will therefore be independent of the nature of the medium, whilst the latter (being governed by the diffusion of vapour to the surface of these nuclei) is assisted by the increased mobility due to the lower pressure in the case of the experiments at 200 mm. and 400 mm. The combined result is that fewer nuclei have time to be formed in the short interval before supersaturation is relieved.

Professor Dr. G. Jander and Dr. K. E. Stump (*Greifswald*) (*communicated*): This work emphasises the great importance of such photo-chemical reactions in the investigation of those aerosols in which the readily volatile material forms a substance of very low vapour pressure and a gaseous product, e.g. by the interaction of the oxygen of the air in

<sup>1</sup> *J. Chem. Soc.*, 1904, 86, II., 488.

<sup>2</sup> M. Volmer, *Electrochem.*, 1929, 35, 555.

the photolysis of iron pentacarbonyl vapour to produce iron oxide, dust and carbon oxides.

The authors' results agree with those of our own recent work, qualitatively but not quite quantitatively, therefore fuller quantitative investigation of this whole complex question is needed; we shall therefore repeat the more fundamental measurements with every precaution to avoid experimental error.

**Dr. N. Fuchs (Moscow)** (*communicated*): The chief difficulty in the investigation of the formation of aerosols lies in strictly separating the two quite different processes involved, *viz.*, the condensation of vapours and the coagulation of the primary aerosol. This may be done either by "fixation" of the primary aerosol by very strong dilution or, as done by Cawood and Whytlaw-Gray, by extrapolation of the numbers of particles per c.c. found in a coagulating aerosol to the moment of its formation. The second important obstacle (the difficulty of obtaining uniform supersaturation throughout the whole volume of the vapour) is completely removed in the photochemical method of smoke formation used in this work. We could therefore say that the experiments of Cawood and Whytlaw-Gray were made under ideal conditions except for the relatively long (6 min.) time spent in the formation of the smoke.

The chief result of these experiments (the increasing of the dispersity of the primary smoke with the air-pressure) can be interpreted unequivocally from the view-point of the modern theory of nuclei formation in supersaturated systems.<sup>3</sup> Since, according to this theory, the number of nuclei formed in unit of time must be independent of the air-pressure, the result mentioned can only be caused by different rate of growth of the nuclei. For particles considerably smaller than the mean free path of the gas-molecules, the rate of growth is also independent of the air-pressure: <sup>4</sup> a perceptible difference in the rate of growth at different pressures will begin only when the growing particles have reached the size of about  $10^{-6}$  to  $10^{-5}$  cm. Henceforth they will grow the faster, the larger the co-efficient of diffusion of  $\text{Fe}(\text{CO})_5$  vapour, *i.e.* the less the air-pressure.

**Dr. W. Cawood (Leeds)** said: With reference to Mr. Goodeve's suggestions as to the formation of condensation nuclei from the molecules of ferric oxide itself, I am in complete agreement. Indeed, we meant to imply such nuclei in the paper.

The difference between condensation from supersaturated vapour and coagulation, I consider to be quite sharp and defined. In condensation, the molecules of the supersaturated vapour collide and an amount of energy equivalent to the energy of formation of the solid is dissipated, a homogeneous primary crystal or particle being thus formed after a sufficient number of molecules have condensed. In coagulation, however, we have the case of two of these primary crystals colliding. They do not in general form one crystal (except in the rare case of the correct edges coinciding and even then an adsorbed layer of gas might keep them separated) nor do they dissipate energy because they are already in the solid phase. This type of coagulation would form the loose-chain-like aggregates which we observed.

Thus, we see that whilst condensation builds up homogeneous particles or crystals, coagulation (in the case of solids) forms aggregates. Moreover, the first process, with a substance like ferric oxide would be much faster than the second. It appears very likely therefore, that in the formation of such smokes, primary crystals are really formed initially and almost instantaneously by condensation, whilst coagulation is a secondary process.

**Professor R. Whytlaw-Gray (Leeds)**, in reply, said: Little is known about the initial stages in the formation of smoke. As Mr. Goodeve has pointed out, in systems of non-volatile particles such as those of ferric

<sup>3</sup> Becker and Döring, *Ann. Physik.*, 1935, **24**, 719.

<sup>4</sup> Fuchs, *Physik. Z.d. Sowjetunion*, 1933, **4**, 481.

oxide it is very unlikely that any of the small molecular clusters first formed split up again, as is the case with volatile systems, and it might be contended that the process is a continuous one of progressive aggregation from the molecular to the particular state. If this were so, a freshly formed smoke should always be heterogeneous and contain all sizes of particles and this heterogeneity should persist during coagulation, giving an extended size distribution of the Smoluchowski type. On this view I agree that the term "primary particle" would be difficult to define. It appears to me, however, that the process is not a continuous one. As a result of molecular encounters a certain number of larger clusters will be formed which contain sufficient molecules to give crystalline units or super-cooled droplets. These will then act as nuclei or centres of condensation for the molecules and smaller clusters, and the system formed finally will be approximately homogeneous.

This apparently is what happens in the formation of a gold sol; primary particles of crystalline gold are formed and, as Zsigmondy and others have shown, the process is dependent on the rate of formation of nuclei and the rate of crystallisation.

If this interpretation can be applied to a smoke, compact particles, often crystalline, will first be formed, these are the primary particles. These will immediately begin to coagulate, and will form later the complexes of loose or chain-like structure which we see in the microscope. The units composing these complexes can, in the case of many smokes, be separated by peptisation with suitable solutions to form hydrosols (as Kohlschütter has shown) but the size of the particles in these has not been determined.

Coagulation, then, is the linking together of compact solid units, which may be crystalline or amorphous, and seems to me to be essentially different from the processes of molecular condensation by which the smoke is formed. Probably the two processes go on simultaneously to some extent and in the early stages the multiple particles formed by coagulation may be cemented together by condensation.

## THE MOVEMENT OF DUST OR SMOKE PARTICLES IN A TEMPERATURE GRADIENT.

By W. CAWOOD.

*Received 31st March, 1936.*

The existence of a dark space round a hot body in a smoke or dust was first observed and studied by Aitken. Since then the size of the dark space and its relations with temperature difference and pressure have been studied by various observers, but no quantitative explanation of the phenomena has been put forward. The effect is almost certainly not due to the radiant energy of the body, for the particles of dust or smoke are in continuous rotation and consequently have an even surface temperature. Also there appears to be no reason why the dark space should have a sharp edge if the phenomenon be due to radiation. Finally, quite a strong effect may be observed at the edge of a solid body only about  $10^{\circ}$  C. higher than the surrounding air, when the radiation would be extremely small, and moreover the dark space does not appear to be dependent upon the nature of the solid surface.

A consideration of the mechanism of the conduction of heat from solid bodies to gases appears to afford a clue to the true explanation of the effect.

It is well known that when a solid body is heated by a flame, there is a sharp temperature gradient near to the surface of the solid.\* Thus, an old experiment is to boil a kettle with a piece of paper stuck on the bottom. The paper does not char, showing that the hot gas molecules do not actually reach it. The dark space may be observed if the velocity of the flame is not too great, and may reach a thickness of about 2 to 3 mm. If the upward velocity of the flame is increased the dark space gets thinner, but never entirely disappears. This one would expect, because the temperature gradient near to the cold surface is set up at a velocity of the same order as the molecular velocities, whilst the blast velocity of burning gas is much smaller.

It is interesting to note, however, that if a smoky flame is used, although the dark space may be observed with ease, the solid particles of carbon are projected through it and deposited on the cold surface, the reverse effect of the dark space round a hot body in a smoke.

This affords a clue to the latter phenomena, *i.e.*, that there is a force which tends to move small particles down a temperature gradient. In other words, that smoke particles will tend to be repelled by a hot body and be attracted by a colder one.

Let us now consider the conduction of heat between solids and gases in greater detail. Consider an infinite flat plate at a temperature  $T_1$  and a gas below it at a lower temperature  $T_2$ , and from the foregoing let us assume that the total temperature gradient is contained in a small strip of gas near to the hot plate. If now there were no convection currents, that is, mass movements of the gas, then if we take any small surface in the temperature gradient

$$N_1 c_1 = N_2 c_2$$

where  $N_1 N_2$  are the number of molecules per cubic centimetre on each side of the surface with components perpendicular to the surface, and  $c_1, c_2$  are their average velocities corresponding to the difference of temperature  $dT$ . This of course is the relationship which Knudsen<sup>1</sup> finds to hold at low pressures and through small apertures.

Consequently

$$\frac{N_1 c_1^2}{N_2 c_2^2} = \frac{c_1}{c_2}$$

$$\therefore \frac{\rho_1}{\rho_2} = \sqrt{\frac{T_1}{T_2}}$$

and

$$\frac{N_1}{N_2} = \sqrt{\frac{T_2}{T_1}}$$

If, then, there were no convection, the pressure of the gas near the hot plate would be higher than at distances more remote. In practice, no pressure differences are to be detected under a horizontal hot plate even with an accurate oil gauge. This is because convection is present and the above assumptions do not hold good. As Knudsen<sup>1</sup> has shown, the pressure difference can be observed and indeed confirms the square root law, only if convection is obviated by connecting the two vessels containing gases at a different temperature by means of tubes of radius of the same order as the mean free path of the gas.

\* This is known as the skin effect in engineering. Measurements of the heat conductivity from gases to solids appear to give the gradient as about one-tenth of a millimeter wide.

<sup>1</sup> M. Knudsen, *Ann. Physik*, 1909, 28, 75, 999; 1910, 32, 809.

It must be emphasised, however, that although convection destroys the pressure differences it does not destroy the temperature gradient. As is shown by the flame experiments, the gradient may be made steeper by the quick mass movements of the gas, but is never entirely destroyed.

Let us now consider a small cylinder of gas in the temperature gradient, of length about twice the mean free path of the gas. If the cylinder has a sufficiently small radius, convection currents will not affect the movements of the molecules parallel to the axis of the cylinder, for the perpendicular velocity gradient of a convection current is not continuous, but must vary in steps of the order of magnitude of the mean free path of the gas. Consequently the velocity on both sides of such a cylinder will be approximately equal. Such a cylinder will therefore move bodily in the current, but the temperature difference between the ends will be the same, and apart from the average temperature being altered, the cylinder will otherwise be unaffected. Consequently in this very small cylinder one would expect Knudsen's laws to be obeyed.

Consider now a smoke or dust particle in the middle of the cylinder. It will be bombarded by gas molecules moving in all directions but it is only necessary to consider the bombardments due to molecules moving perpendicularly to the plate, and if  $F$  is the force per unit area parallel to the plate then the total force on the one side of a spherical particle is

$$\int_0^{\pi/2} F \cdot 2\pi r^2 \sin \theta \cdot \cos \theta \cdot d\theta \\ = F \cdot \pi r^2.$$

The force on the spherical particle due to the bombardment of the gas molecules may now be calculated in a similar manner to that in which Einstein<sup>2</sup> calculated the force on a vane radiometer.

Thus  $\frac{1}{6}N_1c_1(\pi r^2)$  molecules will collide with the particle on one side and  $\frac{1}{6}N_2c_2(\pi r^2)$  on the other, where  $N$  and  $c$  have their usual significance. The difference of velocities of the molecules accounts for the heat flow.

Thus the heat flow if the particle was not there

$$= (\pi r^2)f = \frac{1}{6}N_1c_1 \cdot (\pi r^2) \cdot \frac{mc_1^2}{2} - \frac{1}{6}N_2c_2(\pi r^2) \cdot \frac{mc_2^2}{2} \\ = \frac{1}{6}N_1c_1(\pi r^2) \left[ \frac{mc_1^2}{2} - \frac{mc_2^2}{2} \right] \quad . \quad . \quad . \quad . \quad (1)$$

where  $f$  = heat or energy flow per unit area ;

$m$  = mass of gas molecules.

If  $c_1$  and  $c_2$  are the velocities appropriate to the temperatures at the place of the last collision, *i.e.*, at the ends of the cylinder then

$$\frac{1}{6}mc^2 = \frac{2}{3}RT$$

$$\text{and} \quad \frac{1}{6}m(c_1^2 - c_2^2) = - \frac{2}{3}R \cdot \frac{dT}{dx} \cdot 2L$$

where  $L$  = mean free path of gas.

$$\therefore f = - \frac{1}{6}N_1c_1 \cdot R \cdot \frac{dT}{dx} \cdot L \quad . \quad . \quad . \quad . \quad (2)$$

<sup>2</sup> A. Einstein, *Z. Physik*, 1924, **27**, 1.

If now we consider the smoke particle then there will be excess of momentum ( $k$ ) away from hot plate

$$\begin{aligned} \text{i.e.,} \quad k &= \frac{1}{2}N_1c_1(\pi r^2) \cdot mc_1 - \frac{1}{2}N_2c_2(\pi r^2) \cdot mc_2 \\ &= \frac{1}{2}N_1c_1(\pi r^2)[mc_1 - mc_2] \end{aligned} \quad (3)$$

and if the impulse due to recoil is neglected then  $k$  = force on particle

$$\begin{aligned} \therefore k &= \frac{\pi r^2 f}{c} \text{ (from (1) and (3))} \\ &= -\frac{1}{2}N_1R \cdot \frac{dT}{dx} \cdot L \cdot \pi r^2 \text{ (if } c = \frac{c_1 + c_2}{2} \text{ and } c \text{ is very nearly } = c_1) \\ &= -\frac{1}{2}p \cdot \frac{dT}{dx} \cdot \frac{L}{T} \cdot \pi r^2 \end{aligned} \quad (4)$$

If a smoke particle moves under a constant disturbing force  $k$ , however, we have

$$k = \frac{6\pi\mu rV}{\left(1 + \frac{AL}{r}\right)}$$

$V$  = velocity ;  $\mu$  = viscosity of gas ;  $A$  = constant.

As the edge of the dark space acts as a semi-permeable membrane the smoke as a whole exerts an osmotic pressure on the edge of the space equal to  $\frac{RT}{N} \cdot n$  where  $n$  = number of particles per 22.2 litres.

For one particle this is the component of the Brownian motion on the edge of the space and is therefore  $\frac{RT}{N}$  and the force of one particle on the space is

$\pi r^2$ . Consequently

$$\begin{aligned} \frac{1}{2} \cdot p \cdot \frac{dT}{dx} \cdot \frac{L}{T} \cdot \pi r^2 &= \frac{6\pi\mu rV}{\left(1 + \frac{AL}{r}\right)} + \frac{RT}{N} \cdot \pi r^2 \\ \therefore V &= \frac{\left(\frac{1}{2} \cdot p \cdot \frac{dT}{dx} \cdot \frac{L}{T} \cdot \pi r^2 - \frac{RT}{N} \cdot \pi r^2\right)}{6\pi\mu r} \cdot \left(1 + \frac{AL}{r}\right). \end{aligned}$$

The velocity given by the above equation is the velocity in the small cylinder of gas which we have considered. If, as actually happens, there is a convection current towards the plate, the actual velocity will be reduced, because the cylinder will be moving bodily in the current and if the convection is fast enough the dark space should not be observed at all. As will be seen later this is confirmed by experiment. Also, although the velocity appears to be proportional to the radius of the particle this is not actually the case, for the fundamental assumption is that the radius should be of the same order as the mean free path of the gas (i.e. about  $10^{-5}$  cms.). If the radius is much larger than this, then if the dust-free space is due to molecular bombardment, the force will be destroyed by the convection effects and very large particles ought not to move away from the hot body. According to other observers this actually is the case.<sup>3</sup>

<sup>3</sup> H. H. Watson, *this discussion*.

If the temperature gradient is linear over the region of the dark space, then the time taken for a particle to move from the plate to the edge of the dark space may be calculated as follows.

From the last equation (neglecting the  $\frac{RT}{N} \cdot \pi r^2$  term)

$$V = \frac{dx}{dt} = \frac{K}{T}$$

where

$$K = \frac{\frac{1}{2}p \cdot \frac{dT}{dx} \cdot L \cdot r}{6\mu} \cdot \left(1 + \frac{AL}{r}\right)$$

and if  $\frac{dT}{dx}$  is constant

$$\text{then} \quad T_x = \frac{dT}{dx} \cdot x + T_G$$

where  $T_G$  is temperature of gas.

$$\begin{aligned} \therefore \frac{dx}{dt} &= \frac{K}{\left(\frac{dT}{dx}\right) \cdot x + T_G} \\ \therefore t &= \left( \left(\frac{dT}{dx}\right) \cdot \frac{x^2}{2} + T_G \cdot x \right) \cdot \frac{1}{K} \\ &= \frac{\left(\frac{dT}{dx}\right) \cdot \frac{x^2}{2} + T_G \cdot x}{\frac{1}{2}p \cdot \left(\frac{dT}{dx}\right) \cdot L \cdot r \left(1 + \frac{AL}{r}\right)} \cdot 6\mu \quad (5) \end{aligned}$$

Some rough experiments have been carried out in order to see if the last equation gives values of the right order. A small ultramicroscope cell was constructed in which the top of the cell was a flat brass plate, which was also the bottom of a hollow chamber through which steam could be passed. The cell was illuminated by an arc beam, which was focused so that the edge of the beam was just touching the brass plate. Into this cell was blown tobacco smoke. The dark space was immediately observed, and with steam going through the plate, the thickness was about 0.08 cms. in the middle. Towards the edge the thickness was rather smaller, due presumably to the slightly lower temperature of the edges of the plate, which were in contact with the ebonite cell. Underneath the dark space there was a general convection current, upwards towards the hot plate, but the particles rising in the current did not penetrate into the dark space. The whole appearance was as though there was an invisible barrier, through which the gas rose but not the particles. By blowing into the cell, the dark space was momentarily destroyed, and then all the particles began to move away from the plate with a roughly uniform velocity. The time taken for the particles to move from the edge of the plate to the edge of the dark space was about 3 seconds. As the convection current upwards was of about the same order the true velocity through the gas was about twice that actually measured. Consequently the time taken to move through the dark space was about 1.5 secs.

Let us now see how this agrees with the foregoing calculations. From equation (5)

$$t = \frac{\left(\frac{dT}{dx}\right) \cdot \frac{x^2}{2} + T_G \cdot x}{pL \left(\frac{dT}{dx}\right) r \left(1 + \frac{AL}{r}\right)} \cdot 12\mu.$$

The cell was warmed by contact with the hot plate and thus the temperature of the gas  $T_a$  was on the average about  $50^\circ$  C. and  $\frac{dT}{dx} = \frac{50}{0.08} = 625$ . The average temperature in the dark space being about  $75^\circ$  C., the viscosity  $\mu$  may be taken as  $2.1 \times 10^{-4}$  dynes/cm.<sup>2</sup> The particles were of about  $10^{-6}$  cms. radius.

Consequently

$$t = 0.59 \text{ secs.}$$

We thus see, that whilst the equation gives a value of the right order, the velocity is actually about three times too great. This is probably because the value taken for  $\frac{dT}{dx}$  is too large owing to the temperature gradient not being linear. On the whole, considering the roughness of the experiments, the agreement is satisfactory.

Whilst the above gives the explanation of why the particles move away from a hot body, it does not enable one to calculate the width of the dark space. This appears to be almost impossible because it obviously depends so much upon the convection currents, and consequently the design of the apparatus. It appears as though the temperature gradient is set up at regions very near to a hot body at a speed of the same order as molecular velocities, but that this speed, farther away from the body is much slower, being only of the same order as the ordinary convection effects and the gradient is consequently affected by them.

## THE DUST-FREE SPACE SURROUNDING HOT BODIES.

BY H. H. WATSON.

*Received 9th March, 1936*

### 1. Summary.

If a hot body is placed in a chamber containing dust or smoke, and if it be illuminated suitably, a well-defined dust-free space is seen surrounding the body and extending above it as a sort of wedge. The particles in the chamber follow the convection currents set up by the hot body, but do not cross the apparent barrier of the dust-free space. The thickness of this space was found to increase as the 0.52 power of the temperature difference between hot body and ambient air, and inversely as the 0.61 power of the air pressure. The magnitude of the space is independent of the nature of the dust or of the particle size; it depends, however, on the size and shape of the hot body, being wider the larger the body, and increasing at twice the rate for vertical plane surfaces that it does for horizontal circular rods. At atmospheric pressure the thickness of the dust-free space  $A$  is connected with  $\theta$ , the temperature excess of the hot body over the ambient air, and  $H$ , the convective heat loss per unit area of the hot body per sec., by the following equation:

$$A = L\theta H^{-0.36}$$

where  $L$  is a constant, independent of the size of the body, but double the value for vertical plates that it is for horizontal rods.

A review of the various suggestions as to the cause of the dust-free space has been made. There is evidence that it is caused by a differential molecular bombardment on the particles in the very steep and varying temperature gradient near the hot body.

One practical significance of the dust-free space is discussed in a brief reference to the design of the thermal precipitator dust sampling apparatus.

## 2. Description of Phenomenon.

When a hot body is placed in a chamber containing dust or smoke, and illuminated suitably, it is seen that there is a well-defined dust-free layer embracing the body, and extending above it as a sort of wedge (Figs. 1 and 2). The dust or smoke particles in the chamber follow the convection currents set up by the hot body, but do not cross the apparently impenetrable barrier of the dust-free space.

Tyndall<sup>1</sup> and Rayleigh<sup>2</sup> observed only the wedge of dust-free air above the body, and Aitken<sup>3</sup> and Lodge and Clark,<sup>4</sup> working almost concurrently, were the first to observe and describe that part of the dust-free space which embraces the body.

Aitken was able to show that the effect is not due to gravitational forces, centrifugal forces, vaporisation of the particles, radiation, or electrical forces, and concluded that it is caused by the stronger molecular bombardment on the particles in a direction away from the hot body.

FIG. 1.

Lodge and Clark made a few measurements and concluded that the space increases with increasing temperature of the body, and with decreasing air pressure, and decreases with increasing molecular weight of the gas in which the phenomenon is studied.

The present investigation shows that the thickness of the dust-free space increases with increasing temperature difference between the body and ambient air (equivalent to the walls of the enclosing chamber), at a rate which is rapid at first, but begins to fall off, until at about 70° C. temperature difference it becomes sensibly constant, up to at least 250° C. difference, beyond which measurements were not made (see Fig. 5). The magnitude of the effect depends on the size and shape of the hot body, but not on the nature of that body. Horizontal circular rods and vertical plane surfaces were used in these experiments.

Although the particulate clouds used (principally magnesium oxide) were heterogeneous, with at least a 20 to 1 size range (0.1 $\mu$  to 2.0 $\mu$  diameter), the edge of the dust-free space is sharp and well defined, indicating that, up to at least 2.0 $\mu$ , particles of all sizes are influenced to the same degree. Similarly, the nature of the particulate cloud does not affect the thickness of the space; such widely different substances as magnesium oxide, flint dust, carbon black, tobacco smoke and sulphur "smoke" were used.

<sup>1</sup> Tyndall, J., *Proc. Roy. Inst.*, 1870, 6, 3.

<sup>2</sup> Rayleigh, Lord, *Proc. Roy. Soc.*, 1882, 34, 414.

<sup>3</sup> Aitken, J., *Trans. R. S. E.*, 1884, 32, 239.

<sup>4</sup> Lodge, O. J. and Clark, J. W., *Phil. Mag.*, 1884, 17, 214.

The space has the same thickness round more than half of a horizontal rod and opposite most of the surface of a vertical plate, in fact, opposite all parts of a hot body not affected by the convection wedge.

There are two complications which may occur in the study of this phenomenon, both of which were observed and accounted for by Aitken. First, the apparent dust-free space may be enlarged considerably, because of the vaporisation of particles with a low boiling-point. Lenher and Taylor<sup>5</sup> observed this effect, caused by the evaporation of sulphuric acid mist near a hot platinum wire. The cloud produced by burning sulphur in the chamber will give two spaces for high temperatures of the body, the inner one, which is the true dust-free space, quite free from particulate matter, the outer one containing ordinary smoke, but no product of low boiling-point (*e.g.* sulphur tri-oxide) (Fig. 2). Secondly, if moisture or some other liquid is constantly evaporating from the hot surface, an enlarged space is obtained. In this respect it is interesting to note the effect when carbon tetrachloride is evaporating from a rod, which is initially at the same temperature as the surrounding air. A well-marked dust-free space is produced, but the wedge is pointing downwards, as the rod is cooled by the rapid evaporation. This observation supports the theory that the effect is due to a molecular bombardment. No dust-free space is produced merely by cooling the body.

### 3. Description of Apparatus.

The dust chamber, in which the experiments were made, consisted of a water-jacketed brass cylinder, A, 7.6 cm. long and 8.6 cm. internal diameter (Figs. 3 and 4), clamped firmly with its axis horizontal. The front end was closed by a glass window, B, while a wooden bung, D, with a central brass bush, C, was fitted into the other end.

FIG. 3

Five different bodies were used :

- Body A. Vertical plane copper surface, 6.0 cm. high, 3.0 cm. wide.
- Body B. Vertical plane copper surface, 3.1 cm. high, 3.0 cm. wide.
- Body C. Horizontal circular copper rod, 0.90 cm. diameter.
- Body D. Horizontal circular copper rod, 0.46 cm. diameter.
- Body E. Horizontal nichrome wire, 0.0254 cm. diameter.

The rods passed through the bush, and were held in position along the axis of the chamber by a clamping screw. The wire was also supported along the axis, the ends passing out of the chamber through two holes in the bung. The plane surfaces were supported vertically, in the centre of the chamber and along its axis, by a bracket fixed to the bush.

<sup>5</sup> Lenher, S., and Taylor, G. B., *J. Amer. Chem. Soc.*, 1929, **51**, 2741.

The rods were heated electrically by a resistance coil, K, wound round the end of the rod projecting from the chamber, the heat being conducted along the rod. The wire (Body E), was heated by an accumulator, while

FIG. 4.

the two vertical planes each were made up from two similar plates with a heating coil sandwiched between them.

A small copper-constantan thermo-couple, M, was used to measure the temperatures of the rods and plates; those of the wire were computed from its electrical resistance.

At a distance of 2.5 cm. from the front of the chamber were two windows, F, G. These were arranged at opposite ends of a horizontal diameter of the chamber, and the light from Zeiss 10 amp. automatic arcs, H, illuminated the hot body through the windows. The

windows were covered by a stop, L, so that a ribbon of light, rendered only slightly divergent by a lens, entered the chamber.

FIG. 5.

A horizontally moving travelling microscope, with its axis parallel to and on the same level as that of the chamber was used to observe and measure the dust-free space. Visibility of the space was better and measurements easier to make when dense clouds were used. Multiple scattering of light inside the chamber was reduced to a minimum by painting the walls a dull black.

The water jacket, through which tap water was running, kept the walls of the chamber at a constant measured temperature.

The thickness of the dust-free space was measured for the five bodies for temperature differences up to about  $250^{\circ}\text{C}.$ ; all measurements were made horizontally outwards from the surface of the body.

#### 4. Results.

Measurements of the thickness of the dust-free space were made, using magnesium oxide smoke, produced by burning magnesium ribbon (Table I.).

#### 5. Accuracy of Measurements.

The thickness of the dust-free space was measured to within  $0.0005\text{ cm.}$  The focusing of the microscope was somewhat coarse due to the large depth of focus of the optical system, and errors of about  $\pm 3$  per cent. were possible. This error would be the same for the whole of one set of observations, during which the microscope was usually not re-focused. Temperatures were measured to the nearest degree Centigrade.

#### 6. Interpretation of Results and Empirical Formulæ.

The results show that the dust-free space increases in thickness with increasing temperature difference between the hot body and the ambient air. For any one temperature it also increases with the linear dimensions of the hot body (diameter of a horizontal rod, and height of a vertical plate).

Figures for smokes and dusts other than magnesium oxide have not been reproduced, but within the experimental error of about  $\pm 3$  per

\* These results are plotted in Fig. 5.

cent. they agree with those for magnesium oxide. The figures of Table I. were plotted on logarithmic scales and the following general relation between  $A$  and  $\theta$  obtained:—

$$A = K\theta^\alpha \quad . \quad . \quad . \quad . \quad . \quad (1)$$

where  $A$  is the thickness of the dust-free space,  $\theta$  is the temperature difference,  $K$  and  $\alpha$  are constants.

The values of  $K$  and  $\alpha$  for the different bodies are given in Table II.

Miyake<sup>6</sup> has made recently some measurements of the dust-free space surrounding vertical platinum ribbons, 3 to 10 cm. long and 0.5 cm. wide. He found that the thickness of the space increased as the 0.7 power of the temperature difference.

To obtain a single formula for all bodies, the way in which  $K$  varied with the shape and size of the body was studied. The rate of convective heat loss from a hot body is given by:—

$$H = C\theta^{1.25} \quad . \quad . \quad . \quad (2)$$

Mean value of  $\alpha = 0.52$

where  $H$  is the convective heat loss per sec. from unit area of the hot surface, and  $C$  is a constant which

varies with the shape, size and orientation of the body. The value of  $C$  has been determined experimentally for horizontal rods and vertical planes. It is independent of the length of rod and width of vertical plane, and its values for the five bodies have been obtained from curves given by Fishenden and Saunders,<sup>7</sup> and are tabulated in Table III.,  $\theta$  being given in °C. and  $H$  in calories per sq. cm. per sec.

E	$5.87 \times 10^{-4}$

TABLE IV.

Body.	Value of $L$ .
A	$15.2 \times 10^{-5}$
B	$15.9 \times 10^{-5}$
C	$8.2 \times 10^{-5}$
D	$7.1 \times 10^{-5}$
E	$7.4 \times 10^{-5}$

The best relationship between  $C$  and  $K$  is:—

$$K = LC^{-0.38} \quad . \quad . \quad . \quad . \quad (3)$$

where  $L$  is a constant.

The equations now reduce to:—

$$A = L\theta H^{-0.38} \quad . \quad . \quad . \quad . \quad (4)$$

Values of  $L$ , obtained by substituting the actual recorded values of  $A$  and  $\theta$ , and the calculated values of  $H$  in equation (4) are given in Table IV.

<sup>6</sup> Miyake, S., *Report of the Aeronautical Research Institute, Tokyo University*, 1935, 10, 85.

<sup>7</sup> Fishenden, M., and Saunders, O. A., *Calculations of Heat Transmission*, p. 103 (London, H.M.S.O., 1932).

The mean value of  $L$  for vertical planes is thus  $15.6 \times 10^{-5}$ , and for horizontal rods  $7.6 \times 10^{-5}$ . It is interesting to note that  $L$  is almost double the value for vertical planes that it is for horizontal rods. We may obtain, therefore, the thickness of the dust-free space for horizontal rods and vertical planes of any size from equations (5) and (6).

Horizontal rods :—

$$A = 7.6 \times 10^{-5} \theta H^{-0.38} \quad . \quad . \quad . \quad (5)$$

Vertical plane surfaces :—

$$A = 15.6 \times 10^{-5} \theta H^{-0.38} \quad . \quad . \quad . \quad (6)$$

where  $A$  is in cm.,  $\theta$  in degrees Centigrade, and  $H$  in calories per sq. cm. per sec.

### 7. Effect of Air Pressure on the Dust-Free Space.

W. G. Iles has extended this work and has investigated the effect of air pressures less than atmospheric on the thickness of the dust-free space. He used an electrically-heated vertical plane surface 3.1 cm. high (Body B), and made measurements at five different temperatures, determining the thickness of the space at various pressures for each temperature of the body. He found that, at any one temperature, the thickness of the dust-free space opposite the plane vertical surface, 3.1 cm. high, varied inversely as the 0.61 power of the pressure,  $P$ . His results are summarised briefly in Table V.

For the plane vertical surface, therefore, we may combine the variation of  $A$  with  $\theta$  and  $P$  in the one equation :—

$$A = B^1 \theta^{0.52} P^{-0.61} \quad . \quad . \quad . \quad (7)$$

TABLE V.

Temp. Difference $\theta$ (°C.).	Value of $C$ in Formula $A = BP^{-C}$ .
41	0.61
68	0.63
88	0.59
145	0.58
181	0.61
Mean value of $C$ : 0.61	

The relation between thickness of dust-free space and air pressure, calculated from the figures given by Lodge and Clark (*loc. cit.*,<sup>4</sup> p. 226) for a horizontal rod of carbon give :—

$$A \propto P^{-0.65}$$

It appears therefore that the pressure effect and formula (7) is the same for all bodies, although this will have to be verified by further experiments, especially as Miyake,<sup>6</sup> found for a vertical platinum ribbon that :—

$$A \propto P^{-1.0}$$

### 8. Review of Suggested Explanations of Phenomenon.

The idea of a simple differential molecular bombardment on the particles to produce the dust-free space does not explain why the edge of the space is fixed and well defined. It can be proved that, due to the differential molecular bombardment in a temperature gradient, there should be a force on a small particle, which is directly proportional to the temperature gradient  $dT/dx$ . A temperature gradient exists at every point between the hot body and the walls of the experimental chamber, but the dust-free space does not grow to fill the chamber. There must be some retarding action which stops the effect at a small distance,  $A$ , from the hot body. It seems possible that, in the rapidly moving convection stream, the effect of the thermal force does not have time to develop beyond a certain distance.

Very near to a hot surface (within 0.1 cm.) the temperature gradient is very large, although the precise way in which the temperature varies within this distance is not known. In this connection Randas and Malurkar<sup>6</sup> are hoping to explore the first 0.1 cm. from a hot surface. It seems probable, therefore, that there is a definite minimum value of  $dT/dx$  required to produce the effect, the force due to which is just balanced at the edge of the dust-free space by some force which is connected with the rate of the convection stream, and hence the loss of heat due to convection,  $H$ . We may write in a general way:—

$$F(dT/dx) = H \quad . \quad . \quad . \quad . \quad (8)$$

The temperature gradient at any point will depend on the temperature difference,  $\theta$ , between the hot body and the ambient air, and inversely as some function of the distance from the hot body. At the edge of the dust-free space, at a distance  $A$  from the hot body, we have therefore:—

$$F\left(\frac{1}{A}, \theta\right) = H \quad . \quad . \quad . \quad . \quad (9)$$

Equation (9) is of the same form as the empirical equation (4).

Bancroft<sup>7</sup> has suggested that if a particle is heated on one side, the film of adsorbed air on that side will be diminished in thickness, with the result that air will flow round the particle from the cooler to the warmer side, tending to restore equilibrium. The result will be that the particle is sucked away from the hot body. Bancroft considers that this action and that due to a molecular bombardment take place simultaneously. It is unlikely, however, that the film of adsorbed air will be of the same thickness, or held with the same force, by such widely different substances as carbon and magnesium oxide, but the thickness of the dust-free space is the same to within about 5 per cent.

That radiation has no influence in producing the dust-free space is evident from one or two simple experiments. Aitken, for instance, observed that the space was of the same thickness opposite both halves of a hot plate, one half highly polished and the other half blackened.

In a recent paper, Miyake<sup>8</sup> has suggested that the dust-free space is due to the Magnus effect, produced as the result of the velocity gradient near a hot body. At the surface of a hot body there is no air movement, but the upward velocity of the convection current increases with the distance from the surface until, at a small distance away, it reaches a maximum, and afterwards decreases, but at a slower rate. Miyake found this distance of maximum velocity to be about twice the distance of the edge of the dust-free space from hot vertical platinum ribbons. A particle within the dust-free space will be always nearer the hot body than this region of maximum velocity. It will thus have a slightly smaller velocity of air movement, due to the convection stream, past the side nearest the hot body than past the side more remote. This will produce a spin, and the consequent drag on the particle in the moving air stream, or Magnus effect, will move it away from the hot body.

Now, a velocity distribution, zero at the surface and increasing to attain a maximum value at a short distance from the surface, such as that due to convection currents past a hot body, exists when air is flowing past a surface, whether that surface is warmer, cooler or at the same temperature as the dusty air. In each of these cases, the theory would

<sup>6</sup> Randas and Malurkar, *Ind. J. Physics*, 6, part 1; 7, part 6.

<sup>7</sup> Bancroft, W. D., *J. Physic. Chem.*, 1920, 24, 42L.

demand the Magnus effect to produce a drift away from the body. No dust-free space is observed, however, opposite a body which is colder than or at the same temperature as the air streaming past it; it is only formed round a hot body. The Magnus effect, therefore, does not produce a dust-free space.

It seems fairly certain that the phenomenon is produced by a differential molecular bombardment, and for this to be effective the value of  $dT/dx$  must be above a certain minimum; this minimum depending on the temperature difference between hot body and ambient air and the rate of convective heat loss.

### 9. Thermal Precipitator Dust Sampling Apparatus.

Consider a wire, W, (seen in section in Fig. 6) placed in a horizontal position centrally between the two opposite plane surfaces, A and B, of a narrow vertical channel; suppose that the wire is heated to a temperature at which the thickness of the dust-free space in free air is at least as large as the distance between the wire and either plane surface. Then, if air containing dust or smoke is drawn down towards the wire the particles will not be able to penetrate the dust-free barrier extending across the channel. The particles will be deposited just above  $b$  and  $b^1$ , where the dust-free space comes into contact with the surfaces. The air, freed from particles, will pass by the wire.

This, briefly, is the principle on which the thermal precipitator dust sampling apparatus<sup>10</sup> has been constructed. A wire similar to body E, 0.0254 cm. diameter, is used and the deposit of dust or smoke is obtained on cover-glasses arranged just within the dust-free space. The dust record can be examined microscopically.

This dust sampling instrument is practically 100 per cent. efficient, a feature which makes it very suitable both in the laboratory and in factories and mines for estimating accurately the dust or smoke concentration.

My thanks are due to Mr. J. D. Fry, who suggested this investigation, for his continued interest and advice.

### GENERAL DISCUSSION.\*

Mr. C. H. Bosanquet (*Billingham*) said: At high pressures with large connecting tubes between the bulbs the Knudsen thermal pressure difference effect breaks down, not through convection, but owing to the return flow due to gas pressure. The initial rate of thermal transpiration is proportional to the temperature gradient and the cross-section of the tube. The return flow is proportional to the pressure gradient, and the square of the cross section. Unless the capillary is very small, the full Knudsen pressure difference cannot then be approached.

The number of molecules approaching the hot plate must be equal to the number leaving it in the same time, but their mean velocity is less,

\* On two previous papers.

FIG. 6.

giving a transport of momentum away from the plate, and driving away the particles in a manner analogous to the action of a Crookes' radiometer. This should show up as a force on the plate, though a search tube would not necessarily show a pressure, since the temperature gradient at its mouth would be less than that at the surface of the plate.

**Dr. T. L. Ibbs** (*Birmingham*) said: The work of both authors leads to the conclusion that the dust-free space round a hot body is directly associated with the temperature gradient. This effect is similar to the thermal diffusion effect<sup>1</sup> in gases; simple experiments we have made from time to time on smokes appear to confirm the influence of the temperature gradient on the separating effect.

Chapman<sup>2</sup> has considered the question of brownian displacements and thermal diffusion of grains suspended in a fluid, and predicted a separating effect. In a smoke suspension there are therefore all the conditions required for a thermal separating effect; and the dust sampling apparatus described by Watson shows the practical efficiency of a temperature gradient as a separating device. Tentative calculations made by Dr. B. E. Atkins support the idea that the separation produced by a small temperature difference might be considerable. The question raised by Sir Robert Robertson as to the cause of the black marks on walls near radiators and steam pipes appears to be explained by the tendency of dust particles to move down a temperature gradient, causing them to be deposited on a cold surface.

The apparatus used in many experiments on this subject has taken the form of a hot wire in a large enclosure, and the dust-free space has been observed near the wire. The conditions are complex, as there will be a layer of gas practically at rest near the hot wire, surrounded by gas in considerable movement due to convection. This limits, in effect, the extent of the temperature gradient, and consequently the thermal separation, to a small region round the wire. The increase in the width of the dust-free space obtained by reducing the air pressure is probably due to the reduced effect of convection, with a consequent extension of the temperature gradient. To obtain further progress, convection should be avoided as far as possible.

**Professor K. G. Emeleus** (*Belfast*) said: Useful information about the distribution of density in the gas near the hot body—and hence its temperature—also about the possible presence of local eddies in the convective streaming, would probably be obtained by using an interferometer.

**Mr. A. G. Grant** (*Darlington*) said: Prof. Whytlaw-Gray suggested in his introductory paper that the thermal precipitation phenomena might have a practical application to the industrial removal of dispersoids from gases. From the present discussion it seems evident that the dust-free zone breaks down for gas velocities much above zero. From this, it seems as though the phenomena cannot in fact find an industrial application; this being the case, will the authors explain what, apart from the evolution of the thermal precipitator for obtaining dust slides, is the object and value of this work?

**Professor R. Whytlaw-Gray** (*Leeds*), in reply, said: My reference in the introductory paper was not meant to suggest that thermal precipitation has at present any industrial applications. It is, however, of interest as it involves an effect which has hardly been studied and the explanation of which is still somewhat obscure. A closely related phenomenon is the deposition of particulate matter on cold surfaces from hot disperse systems. This too needs investigation.

**Mr. T. C. Angus** (*London*) said : Should the downward air velocity in the thermal precipitator be not substantially greater than the natural upward velocity due to the convection currents from the hot wire ?

**Dr. R. Meldau** (*Berlin*) said : If a hollow metal sphere of about 10 cm. diameter and pierced with fine holes is used as a condenser in a high tension field of 30,000 to 40,000 volts, and a fog or vapour cloud is forced through the holes, the fine particles take up to a very large extent a uni-polar charge. Such an arrangement has been utilised by the firm Koerting of Hannover for inhalation apparatus and Dr. Wedekind, Cologne, reported upon experiments with it in the *Zeitschrift für Balneologie*, Sprüng, 1936, giving remarkable results.

**Mr. C. F. Goodeve** (*London*) (*communicated*) : I think that a quantitative treatment of the dust-free space cannot satisfactorily be made until the experimental arrangement is such that convection is avoided completely and controlled temperature gradients are obtained. The fact that the dust-free space has the same thickness at points around most of the horizontal rod seems an unexpected coincidence. Apparently, the variation in velocity of the convection current exactly compensates the variation in thickness to be expected from the different times the particles are in the temperature gradient.

Bancroft's suggestions, referred to in this paper, that smoke particles are "sucked" in a temperature gradient cannot of course be taken seriously.

**Dr. W. Cawood** (*Leeds*), in reply, said : In answering criticisms regarding the small cylinders of radius of the order of the mean free path in which Knudsen's Laws (*i.e.*,  $N_1 c_1 = N_2 c_2$ ) hold, I would like to point out that this is the fundamental assumption of the attempted explanation of the phenomena. Unless something of this kind is postulated one would expect a force even on objects of a much greater size, such as small vanes, etc. As far as I know, such forces are not obtained.

I will explain the idea of these small cylinders a little more fully. Imagine a cylinder about 1 mm. wide moving with a convection current. Then, considering only the movements of the molecules parallel to the axis of the cylinder, there will be mass movements of the gas in the cylinder, because the velocity at one side will be greater than at the other. As the radius gets smaller the difference of velocity will get less and it seems quite reasonable to suppose that in a cylinder of which the radius is of the order of the mean free path, there will be no difference of velocity and the cylinder of gas will move bodily in the convection current without mass movements inside it.

**Mr. H. H. Watson** (*Porton*), in reply, said : Sir Robert Robertson has referred to the deposition of dust on walls and the pattern staining on ceilings. Particles of smoke and dust in the air of a room are carried upwards by convection currents and are blown about in all directions by draughts. When these particles, often in quite rapid motion, are brought into contact with the walls, ceiling and furniture of the room they are deposited there, if the solid surface is cooler than the surrounding air.

For instance, there is usually a black deposit on the wall just above a hot water "radiator" or pipe. The convection currents bring many more particles into contact with the wall than does normal diffusion, and the conditions are right for deposition there. It is perhaps not so much due to a thermal force causing the particles to move down the temperature gradient on to the cool surface of the wall, as to the fact that the wall is not protected by a dust-free space.

The replica in light and shade on a ceiling of the construction in, and immediately behind, the plaster is a familiar sight, especially in industrial towns. When there is a wooden lath backing to the plaster, that part of the ceiling not backed by the laths is cooled by the air circulating above the ceiling, and dust can be deposited there. The laths insulate the remainder of the ceiling very efficiently, and dust cannot be deposited if the surface temperature is above that of the ascending air, because of the

protecting dust-free space. When the ceiling is backed by steel girders, as in the Chemistry Department of the University of Leeds, we have an inverse effect. That part of the ceiling backed by the girders is kept comparatively cool and a deposit is obtained there. To prevent pattern staining the temperature of the ceiling must be uniform over its surface. Work to attain this end has been done by Bonnell and Burridge.<sup>3</sup>

In rooms heated by direct radiation, as by an open fire, the walls and furniture are warmer than the air. They are thus protected by a dust-free space, and the dust in the air tends to remain in suspension, and is not deposited to the same extent as when the air is heated by convection, *i.e.*, by steam pipes or hot water "radiators," for then the air is usually warmer than the walls and furniture, and there is no protecting dust-free space.

In reply to Mr. Angus: If a thermal precipitator is supported alone in a dusty atmosphere, without a water aspirator or a source of suction, the convection stream from the wire pulls air upwards through the instrument at a rate which is so small that a very sparse dust deposit is obtained. This shows that the suction velocity is large compared with the opposing convection velocity.

In reply to Dr. Ibbs and Mr. Goodeve: I agree that much useful information would be obtained by studying the dust-free space when convection has been eliminated. We also want precise information about the variation of temperature within the first millimetre from a hot surface. For the practical application of the phenomenon, however, the space must be examined as it occurs in free air, and the empirical formulæ 5 and 6, which I have obtained, used.

## THE DETERMINATION OF SIZE DISTRIBUTION IN SMOKES.

BY H. S. PATTERSON and W. CAWOOD.

*Received 10th February, 1936.*

Smokes, unless dispersed under very special conditions which we have previously described,<sup>1</sup> consist of particles varying very considerably in size. The determination of the size frequency or size distribution, that is, the numbers of particles of different sizes present, is a matter of considerable difficulty. Generally speaking, the methods which have been attempted fall into three categories, firstly, those in which a simultaneous measurement is made of a number of particles suspended in air, secondly those in which some property of the particles is utilised to obtain separation of the various sizes, which can then be enumerated, and lastly those in which the smoke is allowed to sediment and an estimate made of the size frequency.

The first method is necessarily photographic, since it is impossible visually to estimate simultaneously a number of particles, and if they are measured successively, they tend to be selected rather than chosen at random. An ingenious photographic attempt was made by Wells and Gerke<sup>2</sup> who photographed the traces as seen in an ultramicroscope,

<sup>1</sup> *Proc. Roy. Soc.*, 1932, **136A**, 538.

<sup>2</sup> *J. Amer. Chem. Soc.*, 1919, **41**, 318.

in a stream of charged particles moving horizontally under photophoresis in a vertical alternating electric field. Each particle traverses a zig-zag path, by measurement of which its size can be deduced if its effective density and electric charge are known. Since there is considerable doubt as to both of these quantities the method cannot be used to give an accurate size distribution.

This method has been developed and improved by Fuchs and Petrianow<sup>3</sup> who apply an alternating potential at right angles to the particles falling under gravity.

From the zigzag traces obtained photographically, both the charge and mass can be calculated and from the tracks of a large number of particles the size distribution can be obtained; this method can be used for particles of radius of  $0.3\mu$  but for smaller particles it is untrustworthy. Whilst for droplets this method is reliable, for aggregates such as are usually present in smokes, the evaluation of the effective density is difficult and hence the calculation of the radius from the mass is uncertain.

For coarse smokes we have attempted to photograph the vertical traces due to particles falling in the field of the ultramicroscope, but our results appeared to be of little value owing to the difficulty of avoiding convection currents.

The second method has been used by Rohmann<sup>4</sup> who charged a narrow ribbon of particles by passing it through an ion stream and then precipitated the particles on to paper by means of an electric field. Under these conditions the charge caught by the particles is probably proportional to the square of their radius and hence on deposition separation of the various sizes should occur. This method has given good results with dust, but is unsatisfactory for the finer disperse systems. Regener,<sup>5</sup> on the other hand, has suggested passing a smoke at varying velocities through a spiral, when particles above a certain size should be removed by centrifugal action, and counting the residue. In this case, the results would probably be vitiated owing to increase in the velocity of coagulation.

For particulate systems consisting of solid nonhygroscopic particles, sedimentation on to a slide, followed by microscopic measurement has frequently been used, and various types of sedimentation boxes in which a column of the smoke or dust is allowed to settle on to a microscope slide or cover glass, have been devised. The deposit is examined microscopically by transmitted light using an objective of high resolving power, and the particles are measured by an eyepiece micrometer. This method is both slow and laborious and, moreover, can only be applied to particles which are well within the limit of resolution of the microscope.

To overcome these difficulties we have carried out investigations along two lines.

### (1) Photometric Method.

In this method, the deposit which in our experiments we obtained in a collector slide by means of the apparatus already described\* was illuminated from the front to give a dark field as for counting. It was

<sup>3</sup> *Koll. Z.*, 1933, **65**, 171.

<sup>4</sup> *Z. Physik*, 1923, **17**, 253.

<sup>5</sup> Freundlich, *Colloid and Capillary Chemistry*, 1922, 774.

\* See page 1056.

then observed with a special eyepiece previously described.\* containing an artificial particle. The brightness of the artificial particle could be varied by means of a neutral wedge and matched in brightness against individual particles in the deposit. In this way, if the law of scattering is known it is clearly possible to deduce the relative sizes of the particles, and divide up the total number into groups according to size. In practice the method proved somewhat laborious, but it is the only way available at the present time for investigating small particles. The most serious objection, however, is that the law of scattering varies considerably for particles having a radius in the neighbourhood of  $10^{-5}$  cm., the index diminishing for homogeneous particles from the sixth power to the square of the radius with a comparatively small increase in size. For coarse smokes with particles well above this limit, the method should, however, be able to be applied easily. A typical coarse smoke is that obtained by burning magnesium ribbon and measurements have been made with this material. The law of scattering in this case has been previously measured over a fairly long size range<sup>1</sup> for particles suspended in the air, but since this smoke consists of loose complexes which on settling tend to flatten somewhat a further complication is introduced. The results obtained, though incapable of precise interpretation, showed clearly the progressive variation of size frequency as coagulation proceeded.

## (2) Graticule Method.

By the examination of smoke deposits by direct light under the microscope using a high resolving optical system, it has been found possible,

FIG. 1.

with the help of a specially designed graticule, to estimate rapidly the size frequency of particles ranging from about  $1 \cdot 10^{-5}$  to  $25 \cdot 10^{-5}$  cm. radius. A suitable deposit can be obtained in the very early stages of a smoke by using a collector slide holder\* 2 mm. deep, and in the later stages 5 or 10 mm. deep, according to the number of particles. In practice for the graticule used a collector slide holder about 1 cm. deep gives a convenient density of deposit for a smoke containing about a quarter million par-

ticles per c.c. Instead of collecting the deposit in the usual way, the bottom collector slide is replaced by a brass plate carrying a No. 1 microscope cover glass. The brass plate in the collector slide holder is pulled in the ordinary way and after allowing time for sedimentation, the cover glass is removed and carefully mounted on a thin glass microscope slide. The optical systems which we have found best for obtaining the clearly defined images essential for satisfactory results consists of a 2 mm. apochromatic objective N.A. 1.40, used with a ( $\times 12$ ) compensating ocular and a substage achromatic condenser of aplanatic aperture as near N.A. 1.0 as possible. There is no gain in using an oil immersion condenser, since the deposit is mounted dry. This combination gives a  $\frac{1}{3}$  cone in the objective, which

\* Patterson and Whytlaw-Gray, *Proc. Roy. Soc.*, 1926, 113A, 312

\* See p. 1056.

is often considered to be the best working condition. As illuminant we have used a pointolite lamp together with a green or blue light filter.

The graticule, which is inserted in the focal plane of a ( $\times 12$ ) compensating eyepiece, consists of a rectangle and a series of ten numbered circles and corresponding discs as shown enlarged in Fig. 1. These appear superimposed on the deposit as seen in the field of the microscope. The images of the circles and discs correspond in size to particles ranging from  $1 \cdot 10^{-6}$  to  $25 \cdot 10^{-6}$  cm. radius when the deposit is viewed with a 2 mm. Leitz apochromatic objective N.A. 1.40 and a tube length of 17 cm. The size of the rectangle under these conditions is  $5 \cdot 10^{-3}$  by  $2 \cdot 22 \cdot 10^{-3}$  cm. and for a different optical system the graticule can be standardised by measuring the dimensions of the rectangle with a stage micrometer. These graticules have been made to our design by Messrs. Rheinberg. The particles contained within the rectangle can be rapidly matched by eye against the discs or circles and their sizes determined. Since as a rule there are only about 6 particles in the rectangle, it is necessary to match a large number of fields, usually about 50, in order to obtain a good average. The numbers of the various sizes are noted down and a record is kept of the number of rectangles estimated. Since the area of the deposit corresponding to the rectangle and the depth of the collector slide holder are known, the number of particles per c.c. of the different sizes is easily calculated. The sum of the numbers per c.c. of all the sizes, gives, of course, the total number of particles per c.c. of the smoke. With a little experience the size

FIG. 2.

distribution may be estimated by this method both rapidly and accurately. If as a check a circle is occasionally superimposed on a particle by moving the mechanical stage, it will be found that the estimate of size is practically never in error. It may be noted that whilst with a coarse smoke all the particles will be seen and enumerated by this method, with a fine smoke the smallest particles are likely to be invisible and in this latter case the total number should be counted by the special ultra-microscope cell or the collector slide method.<sup>6</sup> Actually, of course, the limit of visibility of small particles viewed by transmitted light, lies well below the limit of resolution. On this account, the smallest particles will all be reckoned as being of radius  $1 \cdot 10^{-5}$  cm., whilst some of them may be below this size. It may be noted that the method can only be applied to non-hygroscopic particles of fairly high melting-point. It is not suitable for example for stearic acid, since the particles of this material tend to melt and spread due to the heat focussed by the condenser. Again, with loose aggregates such as the particles of magnesium oxide, an error may be introduced due to some flattening occurring on settlement. For the investigation of spherical particles such as those formed by the dispersion of certain dyestuffs or of fine dusts such as silica, the method is, however, reliable.<sup>7</sup>

Some results obtained with magnesium oxide smoke dispersed by

<sup>7</sup> Cp. Green and Watson, *Medical Research Council Report*, No. 199.

burning 6 ins. of ribbon in a cubic metre chamber are shown diagrammatically in Fig. 2. The more rapid disappearance with time of the smaller particles is evident. In this case only two deposits taken at 10 and 32 minutes from the start were counted.

The further application of this method should afford a means of tracing the change in size distribution during the life history of disperse systems in gases, provided the minimum size of particle is greater than  $0.2\mu$  radius.

## THE COHESION BETWEEN SMOKE PARTICLES.

By R. STEVENSON BRADLEY.

*Received 19th March, 1936.*

The assumption is usually made that smoke particles will stick together on collision. With a liquid dispersion medium there is evidence<sup>1</sup> that this is not always true, and that a reverse may proceed at the same time as a direct coagulation. With smoke particles, however, reflexion after collision has not been observed, but a pair of particles often gyrate round their centre of gravity at what appears to be a slight distance apart. It is of interest, therefore, to study the conditions of temperature, size of particle, surface energy, etc., under which cohesion occurs with solid particles. In the case of liquid particles the lower energy consequent upon the formation of a large drop, due to decreased surface, will usually ensure coalescence, although the reverse occurs when a living cell breaks up into two units.

The cohesion between solid spheres has been derived theoretically by the writer,<sup>2</sup> and studied experimentally with quartz spheres. If we assume a very general law of force  $f$  between molecular centres,<sup>3</sup> the cohesive force of attraction between two spheres of radii  $r_1$  and  $r_2$  is very nearly

$$F = 4\pi^2 q^2 \frac{r_1 r_2}{r_1 + r_2} \left[ \frac{\lambda}{(n-1)(n-3)(n-4)(n-5)d^{n-5}} - \frac{\mu}{(m-1)(m-3)(m-4)(m-5)d^{m-5}} \right],$$

where  $f = \frac{\lambda}{r^n} - \frac{\mu}{r^m}$ ,  $q$  is the number of molecules per c.c. and  $d$  the smallest distance between the centres of the surface molecules of the two spheres. Flattening of the spheres is not considered. The same assumptions, neglecting such refined considerations as the energy involved in the rearrangement of the surface molecules on the formation of a new surface, give for the surface energy of the solid<sup>4</sup>

$$\sigma = \pi q^2 \left[ \frac{\lambda}{(n-1)(n-3)(n-4)(n-5)d^{n-5}} - \frac{\mu}{(m-1)(m-3)(m-4)(m-5)d^{m-5}} \right].$$

Hence

$$F = 4\pi \frac{r_1 r_2}{r_1 + r_2} \cdot \sigma \quad (1)$$

<sup>1</sup> Colloid Symposium Monograph, 1925, 2, 68.

<sup>2</sup> Bradley, *Phil. Mag.*, 1932, 13, 853.

<sup>3</sup> Lennard-Jones, *Proc. Phys. Soc.*, 1931, 43, 461.

<sup>4</sup> Bradley, *Phil. Mag.*, 1931, 11, 846.

The same value of  $d$  will appear in the expressions for  $F$  and  $\sigma$  if the surface molecules of the spheres are in contact at the point of contact. Equation 1 was subsequently derived by another method by Derjaguin.<sup>5</sup>

In practice it was found that  $F$  varied linearly with  $r_1 r_2 / (r_1 + r_2)$  in the case of spheres of quartz and sodium borate.

These conceptions may be applied to the cohesion of smoke particles, since equation 1 is independent of the precise form of the law of force. The most obvious force tending to cause reversal of coagulation is the Brownian motion. Considering first the rotation, for a double particle formed from two spheres of radii  $r_1$  and  $r_2$ , we have  $\frac{1}{2} I \omega^2 = kT$ , where  $\omega$ ,  $k$  and  $T$  are the angular velocity, gas constant and absolute temperature, assuming that the double particle has the mean energy of rotation for the temperature concerned. If the density is  $\rho$ ,  $I = \frac{8}{15} \pi \rho (r_1^5 + r_2^5)$ . The centrifugal force tending to cause disruption is

$$\frac{8}{15} \pi \rho \omega^2 (r_1^4 + r_2^4) = \frac{8}{15} \pi \rho \frac{1}{2} \cdot \frac{kT(r_1^4 + r_2^4)}{\pi \rho (r_1^5 + r_2^5)}.$$

Hence the point at which centrifugal overcomes cohesive force is given by

$$\frac{1}{15} kT \frac{r_1^4 + r_2^4}{r_1^5 + r_2^5} = 4\pi \frac{r_1 r_2}{r_1 + r_2} \sigma \quad (2)$$

This result is independent of the flattening which may occur on cohesion; the deformation differs markedly from that considered by Hertz for the case of two spheres pressed together, for then the pressure acts throughout the mass, whereas with cohesion only neighbouring layers of molecules are attracted towards one another. At the point at which centrifugal force overcomes cohesion the spheres are just about to part company, and there is no flattening, so that the above results are strictly true.

When  $r_1 = r_2 = r$ , equation 2 gives  $r = \left( \frac{5}{7} \frac{kT}{\pi \sigma} \right)^{\frac{1}{2}}$ . The cases of interest are approximately isomorphous solids, since with crystalline particles departure from the spherical shape will be serious. We should expect quite a low value of  $\sigma$ , about 30 dynes per cm. This gives for  $r$  a value of approximately  $10^{-6}$  cm., i.e. all smoke particles of equal size will cohere. Even at  $3000^\circ$   $r$  is only  $5 \times 10^{-8}$  cm. Hence the fact that equipartition is actually replaced by a Maxwellian distribution hardly affects the argument, since an infinitesimal fraction of particles will have sufficient energy of activation at room temperature. Disruption due to collisions will give similar results.

With particles of different sizes similar remarks apply. If  $r_1 \gg r_2$  equation 2 becomes  $\frac{10}{7} \frac{kT}{r_1} = 4\pi r_2 \sigma$ . Hence  $r_1 r_2 = 2 \times 10^{-16}$  at room temperature. A very small particle will cohere with a large one even if it will not do so with one of its own size.

Chains and aggregates of particles give similar results, e.g. with a linear chain of four particles breaking in the middle it can be shown that  $r^2 = \frac{5}{54} \frac{kT}{\pi \sigma}$ , which gives values of  $r$  smaller than before.

Although impossibly high temperatures would be necessary to obtain disruption with particles of the size usual in smokes, the velocities of the particles required is small compared with molecular velocities at room

<sup>5</sup> Derjaguin, *Kolloid. Z.*, 1934, **69**, 155.

temperature, and the requisite velocity can be reached by violent fanning of the cloud, which sets up eddies, so that particles acquire relative velocity. A particle of density 2 travelling at 30 miles per hour will have sufficient kinetic energy to disrupt a stationary doublet of two particles each of radius  $10^{-6}$  cm. if its radius is approximately  $4 \times 10^{-6}$  cm. With greater velocities ( $v$ ) the radius of the heavy particle will be increased according to  $v^{\frac{1}{2}}$ ; at 30 miles per hour a doublet of particles of radius  $10^{-6}$  cm. requires a heavy particle of radius approximately  $10^{-5}$  cm. for disruption. Cohesion in a large aggregate is confined to the separate cohesions between the component particles, and if one of these on the outside of a large complex were hit by another large complex with sufficient relative velocity disruption could occur. The medium may also impart rotational energy to complex particles, causing disruption. Hence for a violently fanned cloud the normal coagulation might be replaced by an approximately stationary state, owing to a rough balance between coagulation and disruption. Unpublished work of Dr. Colvin and the author working under the direction of Professor Whytlaw Gray showed that stationary states could be produced by violent fanning.

Coagulation in smoke proceeds partly because of the size of the particles. In actual practice the particles will be covered with a layer of adsorbed gas, but it is probable that the solids break through this at the point of contact. If this is not so, then the cohesion between the solids is still given by the same formula, but the distance  $d$  becomes  $d_1$  and is no longer equal to the molecular diameter. Hence

$$F = 4\pi \frac{r_1 r_2}{r_1 + r_2} \sigma \left( \frac{d}{d_1} \right)^{m-5}$$

approximately, neglecting the repulsive term. To this must be added a term representing the cohesion of the two adsorbed layers. The latter may represent a repulsion if the adsorbed layers have, e.g. dipoles oriented perpendicular to the surface. A thin film of water could reduce the cohesion very considerably. When the coagulated particles are immersed in water they may be peptised, owing to the growth of the adsorbed layer. Wo. Ostwald and Haller<sup>6</sup> have shown that the volume assumed by many colloidal precipitates is dependent on the dispersion medium, the thickness of the layer round a particle being about  $1\mu$ , and this effect is correlated with the dipole moment of the dispersion medium.

When the smoke particles are crystalline approximate calculations may be made. With two cubic particles of edge  $r$  face to face the cohesive force is approximately

$$F = \frac{\pi q^2 \mu r^2}{(m-1)(m-3)(m-4)d^{m-4}}.$$

Hence  $F = \frac{\sigma}{d} r^2 (m-5)$ . This gives results similar to those obtained with spheres.

# THE SIZE-FREQUENCY OF PARTICLES IN MINERAL DUSTS.

BY H. L. GREEN.

*Received 9th March, 1936.*

Dusts, in the colloid sense, may be classified as disintegration aerosols, and are formed by the release into the air of particles produced by the disintegration or disruption of solid matter. The term "dust cloud" is frequently used to distinguish the actual aerosol from precipitated or deposited dust. Dusts of mineral origin are of particular interest since they have given rise to an industrial problem of some considerable importance. Certain dusts containing silica, either free or combined or in both these states, when inhaled, cause silicosis and allied pulmonary diseases. Such dusts may be produced by the disintegration of rocks or minerals during processes involving crushing, grinding, drilling, blasting, or, in fact, during any process in which disruptive forces are applied to the material. One of the most important physical factors in the causation of pulmonary disease is the size of particles in the dusts, since only those particles below a certain size can reach the finer passages and air sacs of the lungs and start those changes leading to disease. A fraction of the particles which eventually reach the ultimate pulmonary tissue is deposited. It is probable that this deposition within the lungs is selective and particles of certain sizes are more readily retained than others. Furthermore, the harmful action of the particles after they have been deposited is probably dependent upon particle size. For the successful application of measures for the elimination of dust from air likely to be inhaled by workers, account must be taken of the sizes of particles. The design of exhaust ventilation must be such that the drag on the particles is sufficient to carry them out of the general atmosphere. In filtration of dust from the air, selectivity with regard to particle size plays a part, beside which, such factors as the rate of clogging of the filtering medium by particles of different degrees of fineness have to be considered.

The present investigation was undertaken primarily with the view to determining the sizes of particles likely to cause pulmonary disease, and is concerned with mineral dusts which form moderately stable aerosols mostly containing particles of mean diameter extending from about twenty microns downwards. Particles larger than this size have a high rate of sedimentation and are not considered to be of importance. Determinations have been essentially of an industrial character, but, as the results have thrown some light on the intrinsic nature of dusts, they are worth consideration purely from the standpoint of their bearing on general problems of the formation and behaviour of disintegration aerosols.

## Method of Determining Size-Frequency.

Of the numerous methods available for the determination of particle size in aerosols, few are suitable for estimations under industrial conditions. Such methods as the direct estimation of size by measurement of the rate

of fall of particles, either visually or photographically, can only be readily applied in the laboratory. Reliance has, therefore, been placed on the microscopic measurement of the particles after they have been deposited from the dusts. This method is dependent upon the efficiency of the method for precipitating the particles and is limited by the resolving power of the microscope. For deposition, the thermal precipitator, modified from the original design of Whytlaw-Gray and Lomax, has been used.<sup>1</sup> In this instrument the particles are deposited on microscope cover-glasses on either side of an electrically heated wire. Dust-laden air is drawn into the instrument and the particles are deposited in linear streaks above the wire. Provided the rate of aspiration does not exceed 7 c.c. per minute and the wire is heated to a temperature such that the dust-free space surrounding the wire extends across the space between the cover-glasses, precipitation of all particles in the dust is complete between the limits of mean diameter of at least  $20\mu$  and about  $0.2\mu$  or smaller. In using the thermal precipitator samples may be taken over a period of time varying from a few minutes to several hours. Long period sampling is advantageous under industrial conditions since casual fluctuations in concentration and sizes of particles render samples, taken over a short duration of time, of doubtful statistical value.

The method of determining the size-frequency of particles has already been described in a previous publication<sup>1</sup> and need only be mentioned briefly here. After a sample of the dust has been taken with the thermal precipitator, the cover-glasses are ignited at  $500^{\circ}\text{C}$ . for about ten minutes in order to remove combustible or volatile particles of extraneous atmospheric pollution which are almost invariably present under industrial conditions. When cool, the cover-glasses are mounted dry on a microscope slide. Mounting in a liquid medium would tend to disturb the deposit and break up aggregates of particles which were present as such in the air. Although mounting in air enables the particles to be seen in maximum contrast to their surroundings, it has the disadvantage that it does not permit the fullest use to be made of the resolving power of the microscope.

Examination of particles is done under a magnification of 1500 diameters with a microscope fitted with a 2-mm. oil immersion apochromatic microscope objective and a  $\times 17$  eyepiece. For rapidity of working, measurement of particles is made by means of a Patterson comparator graticule<sup>2</sup> set in the eyepiece, the sizes of particles being compared with the known apparent sizes of the discs of the calibrated graticule. It may be noted that a procedure, slightly different from that previously described, has been adopted for the present series of determinations. Instead of stating the diameter of each particle as being equivalent to that of the disc which it most nearly matches, particles have been grouped in small size ranges. According to this method all the particles above a certain size and up to and including another greater size are placed in one group. This enables the limits of size within various ranges to be defined more precisely than by the original method.

It should be emphasised that, owing to diffraction effects, exact measurement of particles below  $0.4\mu$  diameter is not possible with the microscope system employed, although the presence of particles  $0.2\mu$  diameter or smaller is readily detectable. It should also be noted that the particles, often irregular in shape, are treated as equivalent spheres and, in effect, it is the cross-sectional area of the two-dimensional image which is compared with the disc in the comparator graticule. If the particles are plate-like in form, the method may give rise to an over-estimation of sizes of particles, considered as spheres since such particles tend to be deposited with their larger surfaces parallel to the cover-glasses. When particles, such as those

<sup>2</sup> Green, H. L., *J. Industr. Hyg.*, 1934, 16, 29; Patterson, H. S., and Cawood, W., *this discussion* p. 1084.

of asbestos, have a pronounced fibrous form, it is better to make two distribution counts, one of the length and the other of the diameter of the particles.

### Results.

Samples were taken in various industries which provided examples of sandstone, flint, hæmatite, shale, and asbestos dusts. The nature of the dusts will be described *seriatim* below, together with typical results for the size-frequency of particles. The size-frequency depends not only upon the nature of the dust, but on the precise conditions under which the dust is being formed, on the age of the cloud and on the distance from the source of production that the sample is taken. Owing to the existence of particles in dust clouds which have a relatively high rate of sedimentation, the size-distribution of particles is altering continuously with time. Thus size-frequency is very susceptible to changes in local conditions. It is not intended to describe in detail how size-frequency varies with different processes, but rather to give a general idea of size in relation to the nature of the dust producing material and the disruptive forces coming into play.

(a) **Flint dust**, produced in milling calcined flint (chalcedonic silica) containing about 90 per cent. silica.

Median diameter of particles:  $0.8\mu$  to  $1.3\mu$ ; 20 to 30 per cent. less than  $0.5\mu$ ; 70 to 80 per cent. less than  $2\mu$ ; 1 to 6 per cent. above  $5\mu$ .

FIG. 1.—Size-frequency curve for particles in a sandstone dust.

(b) **Sandstone dust**, produced in shaping blocks of white sandstone by blows of a mallet on a cold chisel. This was a moderately fine-grained, highly felspathic sandstone containing subangular grains of quartz.

Median diameter of particles:  $0.6\mu$  to  $1.1\mu$ ; 25 to 45 per cent. less than  $0.5\mu$ ; 70 to 90 per cent. less than  $2\mu$ ; 1 to 8 per cent. above  $5\mu$ .

(c) **Hæmatite dust**, produced in blasting operations in a hæmatite mine; the hæmatite contained 80 per cent. of ferric oxide, 11.7 per cent. of silica, and 0.5 per cent. of alumina. Samples taken from one cloud only.

Median diameter of particles:  $0.9\mu$ ; 30 per cent. less than  $0.5\mu$ ; 82 per cent. less than  $2\mu$ ; 1 per cent. above  $5\mu$ .

(d) **Shale dust**, produced in drilling and blasting operations in a hard heading in a coal mine; a hard, close-grained shale containing 29 per cent. of free silica.

Median diameter of particles:  $0.4\mu$  to  $1.2\mu$ ; 25 to 55 per cent. less than  $0.5\mu$ ; 65 to 92 per cent. less than  $2\mu$ ; 1 to 10 per cent. above  $5\mu$ .

(e) **Asbestos dust**, produced in handling, disintegrating, carding and weaving asbestos. Samples derived from amosite, chrysotile and crocidolite varieties of asbestos have been examined.

Median length of fibres:  $2.5\mu$  to  $3.5\mu$ ; 8 to 15 per cent. less than  $1\mu$ ; 65 to 75 per cent. less than  $5\mu$ ; 87 to 90 per cent. less than  $10\mu$ .

Median diameter (thickness) of fibres: about  $0.55\mu$ ; 43 per cent. less than  $0.5\mu$ ; 82 per cent. less than  $1\mu$ ; 98 per cent. less than  $2\mu$ .

In addition to asbestos fibres in the samples, there was present about an equal number of ordinary dust particles derived from impurities in the asbestos. Various impurities are known to exist in asbestos, as mined, and may consist of talc, serpentine, magnetite and carbonates of calcium and magnesium.<sup>3</sup> The size-distribution of these other mineral particles was as follows: Median diameter:  $0.45\mu$  to  $0.8\mu$ ; 30 to 55 per cent. less than  $0.5\mu$ ; 87 to 98 per cent. less than  $2\mu$ ; 1 to 4 per cent. above  $5\mu$ .

Detailed figures for certain specific samples are given in Table I. Fig. 1 shows a typical size-frequency curve for a sandstone dust, the sizes being determined in this case by the matching method and not by the grouping method.

TABLE I.—SIZE-FREQUENCY OF PARTICLES IN VARIOUS MINERAL DUSTS.

Size Group. (Microns).	Percentage Frequency for Various Dusts.				
	Sandstone.	Flint.	Shale (during Drilling).	Shale (after Blasting).	Hematite (after Blasting).
Up to 0.2	13.6	9.3	7.6	10.0	9.9

## Discussion of Results.

### The Sizes of the Particles.

Although the size-frequency of particles may show variations of a fairly large order between one kind of dust and another, the results have features which appear to be common to all kinds of mineral dusts. One particular feature is the high proportion of particles which are below  $2\mu$  diameter, and, in some cases, below  $0.5\mu$ . It is commonly believed that dusts contain a large proportion of relatively coarse particles. Gibbs<sup>4</sup> distinguished between the various kinds of industrial aerosols according to the size of particles, and classified dusts as containing particles larger than  $10^{-3}$  cm. ( $10\mu$ ) diameter, but later,<sup>5</sup> in a modified classification, considered dusts to be disintegration aerosols containing particles greater in size than  $10^{-5}$  cm. ( $0.1\mu$ ). The present results are in conformity with the latter classification and indicate that dusts possess a high degree of dispersion.

<sup>3</sup> Hurlbut, C. S., and Williams, C. R., *J. Industr. Hyg.*, 1935, 17, 289.

<sup>4</sup> Gibbs, W. E., *Clouds and Smokes*, London (J. & A. Churchill), 1924, p. 130.

<sup>5</sup> Gibbs, W. E., *J. Soc. Chem. Ind.*, 1932, 51, 1042.

A comparable series of size-frequency determinations was made by Bloomfield<sup>6</sup> in the United States by means of the Owens jet dust counter. Although his results show the same high proportion of particles less than  $2.0\mu$  diameter as in the present determinations, they show a very much lower proportion less than  $0.5\mu$ . In one case 10 per cent. less  $0.5\mu$  is recorded and in the remaining twelve cases the highest proportion is 3.0 per cent. These results are somewhat surprising, as it has been shown that the Owens jet dust counter is more efficient in precipitating particles of the order  $0.5\mu$  than those of  $2\mu$  diameter,<sup>7</sup> and the types of dusts were not very different from those recorded in the present series of results. There is a possibility that some of the finest particles were not detected and measured, since the magnification of 1000 diameters used by Bloomfield was somewhat low for this kind of microscopy.

It is of interest to note that the finer particles in dusts cover the same size range as the coarser particles in smokes, which, in general, contain particles of diameter from  $0.1\mu$  to  $1.0\mu$ . Thus dusts of a high degree of dispersion are comparable with very heterogeneous coarse smokes. It may be noted, however, that fine dusts in an enclosed space have an apparently higher coagulation constant than heterogeneous smokes. The rate of diminution of particles with time follows approximately the law,  $dn/dt = -Kn^2$ , where  $n$  is the number of particles per unit volume at time  $t$  and  $K$  is a constant. Whytlaw-Gray<sup>8</sup> gives values for the coagulation constant for heterogeneous ammonium chloride smokes ranging from  $0.55$  to  $1.70 \times 10^{-9}$  cm.<sup>3</sup>/sec. Whereas for flint dust clouds, containing particles not greater than  $5.0\mu$  diameter, values of the order of  $6.0 \times 10^{-9}$  cm.<sup>3</sup>/sec. were obtained by the author. These values were derived from counts by means of the ultramicroscope on the particles generated in a dust chamber. The high value of  $K$  is probably due to the extreme heterogeneity of the dust; furthermore, the process of coagulation is probably different from that in smokes and is due more to larger particles falling past the smaller ones and colliding with them than to collisions by Brownian motion. It may be noted that the samples of dusts in industry were for the most part taken within a short time of the release of particles which were being continuously generated, and, therefore, the samples were of the primary dust particles. In any case, the numbers of particles in dusts are, comparatively speaking, so low that the actual rate of coagulation is very slow. For instance, if the number of particles in the dust were 10,000 per c.c. (a high value) this would only diminish to about 8000 per c.c. after being left in an enclosed space for one hour, assuming that there were no loss of particles by sedimentation. Hence, aggregation by collision in dust clouds is not usually a factor of importance; such losses of particles that occur are due mainly to sedimentation. When aggregates are found in dusts, they are usually present as such in the original material from which the dust is generated. Re-dispersal of a dust that has been precipitated will often give rise to a cloud containing many aggregates.

A question of some importance is whether particles of diameter less than  $0.2\mu$  exist to any extent in dusts. An answer of this question has been attempted in several ways, although the results so far obtained are not sufficiently accurate to warrant their publication in detail. Particles generated by impact of a chisel on a block of sandstone in a dust chamber

<sup>6</sup> Bloomfield, J. J., *U.S. Pub. Health Rep.*, 1933, 48, 961.

<sup>7</sup> Green, H. L., and Watson, H. H., *loc. cit.*, p. 19.

<sup>8</sup> Whytlaw-Gray, R., *J. Chem. Soc.*, 1935, 268.

were allowed to settle on collector slides,<sup>9</sup> and were counted under a form of dark-ground illumination according to the method described by Whytlaw-Gray. These counts did not differ sensibly from those obtained by counting particles, which had settled on cover-glasses, with the direct vision microscope. The collector-slide method probably enables solid particles as small as  $0.1\mu$  diameter to be detected and counted.

Another method has been to count the sandstone particles by means of the photographic Aitken apparatus,<sup>10</sup> which is capable of detecting particles well below  $0.1\mu$  diameter. In this case the difficulty has been to free the air from atmospheric nuclei which are revealed in the condensation process in the Aitken apparatus and which may far outnumber the dust particles in the air. This difficulty mainly arises when an attempt is made to reproduce an industrial process in a dust chamber of large volume. Again, so far, the results have not shown that particles below  $0.2\mu$  diameter exist to any appreciable extent in these sandstone dusts.

In certain determinations of size-frequency of mineral particles produced by blasting operations in coal mines, it was noted that there were large numbers of very fine particles which were just visible under the microscope and appeared to be rather smaller than the finest dust particles. Subsequent experiments with the explosive, when fired alone, showed that these fine particles were derived from the explosive itself and not from the rock, *i.e.*, they were incombustible smoke particles. Thus, even when rocks are disrupted with explosive violence, there is no indication that there are many particles formed which are less than  $0.2\mu$  diameter.

A point bearing on this question is that the size-distribution of particles in dusts tends to follow a probability law. It is true that at the top end of the scale there is a tendency to depart from the law owing to falling out of the larger particles before they reach the sampling apparatus, but, when losses due to sedimentation are not appreciable, the size-frequency curves approximate to asymmetric probability curves of the "cocked hat" type. Thus, distribution of sizes appears to be a purely random one; it may be inferred from the curves that the expectation of producing particles less than  $0.2\mu$  diameter is small.

On the theoretical side, Gibbs<sup>5</sup> considered that there is a natural limit to the extent to which solids or liquids can be reduced in size by disintegration methods. This limit is imposed by the operation of cohesive or surface tension forces upon each separate fragment of material as it is being formed during the process of disintegration, and he considered the lower limit of particle size for such disintegration aerosols to be of the order of  $0.1\mu$ . Researches on the theory of fine grinding have yielded some information as to the limiting size of particle that can be formed by disintegration processes. In some work on this subject, Martin and his associates<sup>11</sup> did not find any end point to the production of fine particles, but as the smallest particles that were measured had a diameter of  $0.85\mu$ , the results of their experiments must be regarded as being inconclusive. On the other hand, Andreassen<sup>12</sup> estimated the sizes of particles by sedimentation in a liquid medium, and deduced that particles as small as  $0.1\mu$  diameter could be formed by grinding.

### Mechanism of Formation of Dusts.

The size-frequency of particles throws some light on the mechanism of the formation of dusts. The process of disintegration of the mineral or rock is accomplished by the application of shearing and tensile stresses, slowly, as in milling processes, or suddenly, as in drilling with pneumatic drills. The effect of the applied forces is to cause disintegration by splitting or cracking along planes of weakness in the material. It is possible to distinguish between two classes of particles, represented respectively by small fragments, and by fine particles released from the freshly formed surfaces by cracking on a micro scale as the material is torn apart. It is likely that the dusts which were estimated in the present series of experiments belong almost wholly to the latter class. On this theory it is possible to account for the observation that the sizes of particles in dusts formed by explosions are comparatively little different from those of particles formed by less violent processes of disintegration. Explosion entails disruption with extremely high velocity, but in essentials the action is the same as in other disintegration processes, that is, fragmentation takes place with release of fine particles from freshly exposed surfaces. It is true that fragmentation is more complete, but the sizes of the finer particles are similar to those of other industrial dusts.

It would be expected that the size and shape of dust particles would depend upon the mineralogical nature and structure of the material from which they are derived. With the exception of the case of asbestos, the present series of results cannot be regarded as being significant in providing information in this respect. There were so many local factors influencing the samples, that it would not be safe to draw more than generalised conclusions from the estimation of size-frequency. Asbestos, however, provides an example of a mineral in which there are definite planes of cleavage, and the splitting process takes place along these planes, yielding fine fibrous particles.

In the case of rocks containing several minerals of different hardness and crystal size, fracture may occur more readily through some of the minerals than through others, and the composition of the dust may be different from that of the original rock. The results so far obtained have not yielded any real information as to the selective fracture of the different mineral constituents. One difficulty in the way of determining the nature of the dust particles in relation to the nature of the parent rock is that such a high proportion of particles are less than  $2\mu$  diameter and, at present, there is no physical method available for identifying the exact nature of individual particles of that size range.

### Summary.

Samples of industrial mineral dusts have been obtained by means of the thermal precipitator, and the size-frequency of the particles determined under a microscope of high resolving power. Data for the size-frequency of particles derived from flint, sandstone, hæmatite, shale and asbestos are given. It was shown that most of the particles are smaller than  $2\mu$  diameter, but there was little evidence that particles of less than  $0.2\mu$  diameter occur in mineral dusts. The dusts are considered as disintegration aerosols of a high degree of dispersion, and the significance of the results has been discussed on this basis. A theory of the mechanism of the formation of dusts has been put forward.

The author is indebted to Mr. H. H. Watson for his co-operation in obtaining samples of the dusts. He is also indebted to the Industrial Pulmonary Disease Committee of the Medical Research Council, on whose behalf this work was undertaken, for permission to publish this paper.

### GENERAL DISCUSSION.\*

**Dr. K. Söllner** (*London*) said: Can Mr. Green throw some light upon a closely related problem, which may, I believe, be noticed fairly regularly in clean country fogs, and in the presence of fine, clean stone dust, even after blowing it through a hot flame. The presence of a badly stoppered bottle of  $\text{Fe}(\text{CO})_5$  in a room may also produce a similar sensation. The odour seems to be fairly independent of the nature of the disperse phase, provided that the latter is chemically inert and that no foreign odorous substances are present. The only very tentative explanation I can so far offer assumes that very fine particles reach the olfactory organ high up in the nose (quite analogous to the case mentioned by Green), and adsorb or dissolve some substance naturally present there: this disturbance of the natural stationary state in the olfactory organ possibly causing a sensation of smell.

**Dr. C. G. Addingley** (*Cleckheaton*) said: I have been using a method somewhat similar to that described by Green, for estimation of asbestos dust in the atmosphere of an asbestos factory; an Owens' jet dust-counter was used, and the cover-glass ignited to remove organic matter. In smoky districts a visible ash deposit is left by the soot particles on the cover-glass after ignition; the number usually varies between about 30 and 150 particles per c.c., but counting is somewhat difficult and uncertain, as the particles are of about the minimum size which the microscope will resolve. The average size of the asbestos particles varies naturally with the process to which the asbestos is being subjected but, in the measurements I have taken, it is much smaller than that given in the paper. I have always found 50 per cent. or more of the particles  $0.5\mu$  or less, 5 to 25 per cent. between  $0.5$  and  $2\mu$ , 2 to 10 per cent. between 2 and  $5\mu$ , and up to 5 per cent. over  $5\mu$ .

**Dr. R. Lessing** (*London*) said he could not agree that the size of particles in dusts formed by explosions differed little from that of particles formed by less violent disintegration. In experiments in a Welsh anthracite mine to study the incidence of silicious dust in various mining operations, he found that the dust produced by drilling the hard shale settled relatively quickly, whilst that released by shot-firing in the same rock remained suspended very much longer. He attributed this to differences in particle size. The dust counts in the air were made with a konimeter, and he admitted that in this instrument particles below a certain size, say  $0.5\mu$  were not observable.

**Professor K. G. Emelius** (*Belfast*) said: It would be interesting to attempt to find some correlation between the size frequency in dust formed by shattering of crystalline material, and the size frequency in the secondary structure of the crystal shattered. Might there not be a tendency for the dust particles to be the actual secondary units in the original substance?

**Professor E. N. da C. Andrade** (*London*) said: The words "mosaic" and "secondary structure" have been used in many different senses, and made to include, for instance, the slight changes in inclination which occur at small intervals on the surface of rock salt, and certain other, crystals. There seems no reason why these changes of direction should be sources of weakness, for in general, the more perfect a crystal, the weaker it is, and polycrystalline materials, where the changes of direction are large,

\* On the three previous papers.

are very strong. A system of actual minute cracks, such as those found in diamond, has also been called a mosaic structure, and in such cases it seems highly probable that the cracks should be places of weakness, and that the material should tend to fracture along them. I do not know what evidence there is for this type of structure in crystals which have been studied in the pulverised state, but Professor Emeleus' suggestion might with profit be followed up experimentally.

**Mr. F. I. G. Rawlins** (*London*) said: The problem of measuring small particles might be facilitated by using a microscope similar to that developed by Barnard. Ultra-violet light is used, and the optical system is quartz or fluorite. It is clear from the Abbe-Rayleigh equation that high numerical aperture is essential and objectives having this feature are now available.

**Dr. F. T. Peirce** (*Manchester*) said: Has any systematic work been done on the efficiency of filtering as a function of pore and particle sizes? This might yield a possible, though hardly a precise, method of determining size distribution, and is of direct interest to questions of filtering, including the retention of dust in the nose.

**Mr. A. Dooley** (*Birmingham*) said: Has the X-ray powder diffraction method been considered as regards its application to the identification of the constituents of dust and smokes? In my experience, the method is satisfactory for particles at least as small as  $0.5\mu$ .

**Dr. W. Cawood** (*Leeds*), in reply, said: Dr. Dobson has asked a question about the different laws of scattering of light by small particles mentioned briefly in this paper. The subject is treated in some detail by Whytlaw-Gray and Patterson in *Smoke* (E. Arnold & Co.), chap. xiii. Briefly, Rayleigh<sup>1</sup> showed that for infinitely small particles the law was  $I \propto r^6$ , where  $I$  is the intensity of the scattered light and  $r$  is the radius of the particle. Mie<sup>2</sup> has shown mathematically that for particles of diameter greater than one-tenth the wavelength of the incident light, the power will decrease with increase of radius to slightly less than two and will then increase to two when the particle is large enough to become a true reflector. Jobst<sup>3</sup> has extended Mie's theories and simplified them. Patterson and Whytlaw-Gray<sup>4</sup> have obtained confirmatory experimental proof.

**Mr. R. S. Bradley** (*Leeds*) (*communicated*): In the grinding of particles mentioned in Green's paper, the work required to overcome the cohesion, and separate a crystallite into two parts, decreases as the size increases, but the work per gm. of material increases rapidly owing to the increasing number of particles. There is an increase in the work required for the disintegration of particles of diameter less than approximately  $10^{-4}$  cm., owing to the secondary structure of the solid (lineage or mosaic structure), involving the presence of pores and cracks. The energy of a "crack surface" is roughly half the true surface energy of the solid, on which depends the work required to disintegrate a perfect crystal, so that further decrease in size after the destruction of the secondary structure, requires a marked increase in work. This may well set a limit to the size of particles obtained by grinding a solid.

**Mr. H. L. Green** (*Porton*) in reply, said: The phenomenon to which Dr. Söllner has referred, must, I think, be associated with the filtration of fine particles in the passages of the nose, and I imagine that the explanation offered by him affords a tentative solution of his problem. Possibly the familiar earthy smell after a light shower of rain in summer may be caused by the impact of the raindrops on the dusty ground and the release into the air of fine dust particles which are subsequently trapped in the nose. It may be that the solubility of these seemingly chemically inert substances in the tissue fluids is sufficient to cause a sensation of smell.

The discrepancy between the general trend of Dr. Addingley's results

<sup>1</sup> *Phil. Mag.*, 1871, 41, 107, 441.

<sup>2</sup> *Ann. Physik*, 1908, 25, 377.

<sup>3</sup> *Ibid.*, 1925, 76, 863.

<sup>4</sup> *Proc. Roy. Soc., A*, 1926, 113, 312.

for asbestos dusts and that of mine would appear to be due to differences of method. In the report written by Watson and myself for the Medical Research Council,<sup>5</sup> we gave the results of the tests on the efficiency of various dust sampling instruments, and showed that, for flint dust, the Owens jet dust counter only precipitates about 40 per cent. of the particles, and is apparently more efficient for the *smaller* particles than the *larger* ones. I have not checked the efficiency of the Owens counter for asbestos, but the accuracy of the results with the thermal precipitator has been confirmed by parallel determinations by a sedimentation method on asbestos dusts generated in a dust chamber. In the particular works where the asbestos samples were obtained, the smoke particles, after ignition, left no residual ash, but such ash particles were noted in dusts determinations in other places, especially at Sheffield.

The experience of Dr. Lessing also differs from mine, but as his findings are based on visual observations on rates of settling which, in my opinion, may give rise to misleading conclusions and, on counts with the konimeter, which gives results of doubtful absolute or even comparative value, I do not think they can be regarded as disproving the validity of my own conclusions. It would be of interest if thermal precipitator samples could be taken in the mines where Dr. Lessing made his experiments.

Professor Emeleus has raised a most interesting point which I hope will be followed up by further investigation of the secondary structure of crystals. The remarks of both Professor Andrade and Mr. Bradley also lend support to the view that the size-frequency of the particles may be related to the secondary structure of the crystals from which they are derived.

I have at various times considered using the ultra-violet microscope, as suggested by Mr. Rawlins, but I decided that, unless it is shown that there are in dusts numerous particles below  $0.2\mu$  diameter, the gain in accuracy by using an ultra-violet microscope would not compensate for the loss of the speed and general utility of the ordinary visual microscope.

Dr. Peirce raises a question which has hitherto received but little attention, although some theoretical work on it has been done by Albrecht,<sup>6</sup> and it was discussed by Gibbs in his book on *Clouds and Smokes*. The subject is of obvious importance, especially in connection with the protection of workers against harmful dusts by means of respirators, and the general problem of the filtration of dusts in industry. I am doubtful whether filters would be sufficiently selective in their action to enable them to be used for the accurate determination of size-distribution of aerial dispersoids.

In reply to Mr. Dooley, the X-ray powder diffraction method has been used for the determination of the percentage of free silica in rock dusts, notably by Clark and Reynolds<sup>7</sup> in Canada, but the method appears to be limited at present to one or two constituents of the dust.

# THE AGGREGATION OF SUSPENDED PARTICLES IN GASES BY SONIC AND SUPERSONIC WAVES.

BY O. BRANDT AND E. HIEDEMANN.

*Received 9th March, 1936.*

New optical methods for rendering sonic and supersonic waves visible have been systematically studied in the last four years.<sup>1</sup> O. Brandt and H. Freund<sup>2</sup> tried, *inter alia*, the addition of tobacco smoke to indicate the wave-length of sound waves of frequencies between 6 and 50 k.c. in air enclosed in a tube; they observed an almost instantaneous precipitation of the smoke, the rapidity of which was the more astonishing as other observers of the coagulation of smoke by supersonic waves of lower frequency (e.g., H. S. Patterson and W. Cawood<sup>3</sup>) found only very much smaller effects. We thought, therefore, that further studies on the process of rapid precipitation should be of interest.

## Photomicrographic and Kinematographic Observations.

The nature of the process was not immediately evident. Microscopic observation showed suspended particles of some size; this proved that aggregation had taken place in the sound field. More information was secured when photomicrograms of the suspended particles were obtained. The use of kinematographic methods yielded especially significant results. In these experiments it was necessary to obtain photomicrographs with very short times of exposure (1/125 second) in order to distinguish between that movement of the particles due to the general circulation between node and anti-node and that due to the oscillation. This was accomplished with the optical arrangement shown in Fig. 1. S represents the end of vibrator rod. R is a vertical sounding tube containing air to which tobacco smoke was added. An observation chamber K made from two ordinary cover-glasses sealed to a celluloid frame of 0.7 mm. thickness was fixed on the bottom of R. Light from an electric arc L was concentrated by a condenser K<sub>0</sub>, a diaphragm B serving to screen the central rays. The aperture of the objective of the microscope must be the same as that of the rays screened by the diaphragm, so that no direct light, but a maximum of the light diffracted by the suspended particles, can enter the microscope.

Fig. 2 represents the circuit of the vibration generator. The vibrator rod (made of Indilatans-steel) was initially magnetised by means of the coil  $L_1$  carrying direct current.

FIG. 1.—Photographic arrangement.

Fig. 3a gives a photomicrograph of the particles immediately after the generator begins to work; the particles are oscillating under the influence of the sonic waves and appear therefore as small streaks with more intensive ends. The length of the streaks is determined by the amplitude of oscillation of the particles.<sup>4</sup> The time of exposure was  $1/125$  sec. Fig. 3b shows the particles half a second later; the particles of the smoke have in the meantime become so much enlarged by aggregation that their inertia inhibits noticeable oscillation. The time of exposure for this photomicrograph was  $1/10$  sec. so that the tracks of the moving particles are marked. The coalescence of two or more streaks shows the continued coagulation.

Fig. 4 shows a series of photomicrographs selected from kinematographic observations. Fig. 4 (a) shows the suspended particles before the sonic waves are produced; Fig. 4 (b) taken immediately

after switching on the generator, the oscillation of the particles is observed. Figs. 4 (c) to (f) show different phases of the process. Figs. 4 (g) and (h) were made after disconnecting the generator. A comparison of these last

FIG. 2.—Vibration generator circuit.

two pictures with the first indicates the increase in size of the particles. The time of exposure for each picture of the series was  $1/25$  sec. Whereas the non-coagulated particles practically remain at the same place during that time (they are photographed as points), the coagulated particles cross nearly the whole range of vision.

<sup>4</sup> E. N. da C. Andrade (*Physic. Soc., London, Report of a Discussion on Audition*, 1931) first pointed out the possibility of measuring the intensity of the sound field by the amplitude of the oscillating particles.

These and many other photographs, as well as supplemental subjective microscopic observation, led us to distinguish two principal phases of the process. In the first phase the particles oscillate under the influence of the sound waves and take part in the general circulation between node and antinode, increasing in size by aggregation which takes place in the sound field owing to collisions of the particles. In the second phase the particles are so much enlarged, that they no longer oscillate, but describe very complicated and irregular tracks, similar to those observed by Andrade with particles of cork at lower frequencies.<sup>5</sup> During the second phase the process of coagulation continues by collisions between the enlarged particles and also between enlarged and still oscillating particles.

#### Measurements of the Rate of Increase in Size of the Particles.

The extent of the increase of the size of the particles under the influence of the sound field was determined by different methods. The measurement of the velocity of the falling particles gives accurate information on the mass of the particle in the case of spherical particles if the Stokes - Cunningham formula is used; if the particles are not spherical the information so obtained is less reliable, but in most cases gives the order of magnitude. In view of the aniso-dispersity of the aerosols we only measured the velocities of the largest or most rapidly falling particles; the results of the measurement do not constitute therefore an average of the rate of enlargement, but are none the less significant.

FIG. 5.—Optical arrangement (S. and Z.).

Of course, the range of vision must be sufficiently large for the observation of a considerable number of falling particles, so that the identification of the largest particles does not offer any serious difficulties. For various reasons the observation chamber and illumination applied in the photographic work could not be used. The optical arrangement of H. Siedentopf and R. Zsigmondy (Fig. 5) seemed to be most suited for these measurements. The objective *O* projects a reduced image of the slit *S* into the observation cell *K*<sub>2</sub>. The space traversed by the falling particles was well defined by two horizontal threads in the microscope. To avoid disturbances by currents of air in the observation chamber a special double cell *K* was used (see Fig. 6). The falling particles enter the cell *K*<sub>1</sub>. The illuminating band of light passes first through the window *F*, which is covered by a glass *G*<sub>1</sub>, into *K*<sub>1</sub> and then through the glass *G*<sub>2</sub> into the chamber *K*<sub>2</sub>, where it is absorbed at the opposite blackened wall. In the direction of observation the cell is covered by a cover-glass. All walls which could cause disturbing reflections are suitably blackened. Fig. 7 shows how the observation cell is fixed to the sounding tube.

As it was desirable to measure many particles successively the time of fall was registered by a Morse apparatus. The Morse-key was pressed as long as the particle moved from the upper to the lower thread in the microscope. The time could be determined from the registered lines with great accuracy by a simple arrangement which printed marks on the same

<sup>5</sup> E. N. da C. Andrade, *Phil. Trans.*, 1932, **230A**, 413; *Proc. Roy. Soc.*, 1931-32, **134A**, 445.

paper at regular and known time-intervals. The different intensities of the sound field could be compared by measuring the amplitude of oscillation of the end of the vibrator rod. This was done by adjusting a microscope to an illuminated point on the surface of the end of the rod, when the rod is oscillating the point appears as a line, the length of which can be determined by a micrometer in the eye-piece of the microscope.

FIG 6—Observation chamber

FIG 7—Sounding tube

Table I shows the relationship of the increase in size to the sound intensity, the first column gives the amplitude of the oscillating rod, the other column the ratio of the increased mass  $m$  to the initial mass  $m_0$  of the particle. In each experiment the aerosol (tobacco smoke) had been under the influence of the sound waves for a time of 5 seconds. Higher intensities of sonic waves were intentionally not used for the measurements. The data of the last column were calculated by the Stokes-Cunningham formula. As to the deviation of the coagulated particles of tobacco smoke from spherical shape see below.

1	4
2	13
10	110

More reliable results may be obtained by using an aerosol in which liquid (and therefore strictly spherical) particles are suspended. By dispersing paraffin oil a fog was produced, the concentration of which was only 1/7 of that of the tobacco smoke used. Table II represents some results obtained with this aerosol, and shows how the increase in size depends upon the length of the time during which the sonic waves operated on the system. In all measurements the amplitude of the vibrator rod was  $36 \times 10^{-3}$  mm.

The dependence of the increase in size of the particles upon the intensity (Table I) proves that with increasing intensity the process may be expected to be highly efficient. Such experiments were successfully made

by means of the air-jet-generator and a powerful magnetostriction-generator and are described below.

### Optical Measurements.

Whereas the above measurements give information only as to the increase in size of the largest particles present, one may obtain results as to the average by using nephelometric methods. The high aniso-dispersity which is rapidly brought about under the influence of the sound waves permits only somewhat rough results. Since increase in size under the influence of the sound field is a rapid process, it is necessary to use an arrangement allowing a record of instantaneous changes of the optical properties (the absorption of light) of the aerosol. This condition could be realised by measuring the intensity of light with a photo-electric cell connected to a Galvanometer (Moll) of a very short period of oscillation ( $1/50$  sec.). The deflection of the galvanometer was recorded on a rotating film. The absorption was measured by applying a differential circuit containing two photo-electric cells, represented by Fig. 8. Light from

FIG. 8.—Circuit for Nephelometric measurement.

the source L is made parallel by a large (150 mm. diameter) lens (not shown in the Fig.) and then caused to traverse the sounding tube. A similar lens (not shown) forms an image of the source on the diaphragm of the photo-electric cell. A broad beam of light was chosen in order to have several nodes and antinodes in the observed region and to eliminate the influence of local air currents. From the same source, L, light also enters the photo-electric cell Z<sub>2</sub> through the diaphragm B<sub>2</sub>, which has a variable aperture. The electric differential circuit is so simple that it needs no explanation. The aperture of the diaphragm B<sub>2</sub> is varied until the galvanometer gives no deflection when there is no aerosol in the tube. When aerosol is brought into the tube the galvanometer deflection increases with increasing absorption of light. By means of neutral tint glasses (the absorption of which was well known) it could be shown that the deflection of the galvanometer was proportional to the absorption of light.

The absorption of light by suspended particles of large size can very approximately be calculated if one considers only the geometrical shape

of the particles which are supposed to be opaque.<sup>6</sup> The coefficient of absorption is then given by  $n \cdot q$ , if  $n$  is the particle-concentration and  $q$  the cross-section of a particle. O. Werner<sup>7</sup> has experimentally proved that this theory of G. Mie gives very satisfactory results when applied to evaluate practical measurements. Using the assumptions of Mie he derives the following formula for the extinction  $E$  of light:

$$E = n \cdot r^2 \cdot \pi \cdot s \cdot \log e \quad (1)$$

where  $s$  is the length of the path of the light in the aerosol and  $r$  the radius of a suspended particle. For a constant value of  $r$  the extinction  $E$  is proportional to the particle-concentration. To obtain the increase in size of the particles by absorption measurements, we must consider that the radius  $r$  changes with  $n$ . If the mass-concentration ( $g./cm.^3$ ) at least remains

FIG. 9.

constant a simple relation is obtained. For constant mass-concentration  $c$  one gets:

$$c = 4 \cdot \pi r^2 \cdot d \cdot n / 3 \quad (2)$$

From eq. (1) and (2) one obtains:  $E = \text{const.}/r$  or

$$E_1/E_2 = r_2/r_1 \quad (3)$$

This means that the extinction of light is inversely proportional to the average radius of the particles. Since this relation is only valid so long as the mass-concentration of the system remains constant, only very low intensities of the sound field could be used. Fig. 9 shows some results of measurements made with an aerosol consisting of paraffin oil particles suspended in air. The ordinates give the ratio of the increased to the initial mass and the abscissae the duration of the influence of the sound field. The different curves represent different sound intensities. In curve I, the amplitude of the vibrator rod was  $9 \times 10^{-3}$  mm., in curve II.  $27 \times 10^{-3}$  mm. and in curve III.  $36 \times 10^{-3}$  mm.

<sup>6</sup> G. Mie, *Ann. Physik*, 1908, **25**, 377.

<sup>7</sup> O. Werner, *ibid.*, 1923, **70**, 487.

The optical method yielded results in good qualitative agreement with the results of measuring the velocity of the falling particles.

### Coagulation in Flowing Aerosols.

The rapidity of the acoustical precipitation permitted the study of the process in flowing aerosols. As the rate of coagulation increases with the sound intensity it was necessary to use sonic waves of high intensity. Experiments with powerful magnetostriction-generators using longitudinally divided tubes to which end-pieces of large area were affixed gave very satisfactory results. The extremely simple and efficient source of intense sound waves we have used was the air-jet generator described by Jul. Hartmann,<sup>6</sup> in which a high pressure air-jet is employed which has a velocity greater than that of sound. Along such an air-jet a periodicity of pressure can be observed. If the mouth of a cylindrical pipe is brought to a place where the Pitot-pressure is increasing, very powerful sound waves will be generated in the cylinder, the frequency of which depends, of course, upon the dimensions of the cylindrical resonator. Fig. 10 shows the air-jet generator built into a simple apparatus which has also proved to be convenient for lecture experiments.<sup>7</sup> To two sides of the

FIG. 10. —Air-jet generator.

generator are affixed tubes (1 metre long and 30 mm. in diameter) which can be tuned by pistons at the opposite ends so that stationary waves will be produced. The aerosol to be studied enters the sounding tubes by means of inlets near the pistons and then flows towards the generator. If the generator is working nearly all the suspended particles will coagulate and be precipitated at the bottom of the tubes. With this simple apparatus somewhat large amounts of aerosols could very efficiently be precipitated: e.g., 200 litres per minute of highly concentrated aerosols such as tobacco smoke or  $\text{NH}_4\text{Cl}$  particles suspended in air. The efficiency of the precipitation was measured by nephelometric methods. Comprehensive studies on the precipitation of many aerosols of a very different nature have been made; these will shortly be reported elsewhere. Every true aerosol may be coagulated and precipitated in the above manner.

### The Shape of the Aggregated Particles.

The above-mentioned evaluation of the velocity of the falling particles and of the extinction of light was based on the assumption that the particles are spherical. For liquid particles this assumption may safely be made. We thought it interesting to study the appearance of acoustically aggregated dry particles such as  $\text{NH}_4\text{Cl}$  and tobacco smoke. Fig. 11 is a photomicrograph of coagulated tobacco smoke. The particles clustered in the gas space have settled down on a cover-glass. The

<sup>6</sup> Jul. Hartmann, *Physic. Rev.*, 1922, 20, 719; *Phil. Mag.*, 1931, 11, 920.

<sup>7</sup> The apparatus was first used in a lecture experiment by E. Hiedemann in the *Haus der Technik* in Essen on the 13th November, 1935.

precipitated particles resemble a very viscous medium in which granular particles are embedded. The drop-like aspect of the smaller particles suggests that their shape in the gas space does not materially differ from the spherical. As has been shown by earlier investigators (see *e.g.*, Whytlaw-Grey and Patterson) one has to expect in dust a non-spherical structure. The high degree of aggregation produced in the sound field leads to a very flocculent structure of the clusters. Fig. 12 is a photomicrograph of  $\text{NH}_4\text{Cl}$  clusters formed by the sound field. The structure is evidently chain-like. Fig. 13 is a photomicrograph of suspended  $\text{NH}_4\text{Cl}$  particles made before the generator was connected. Figs. 12 and 13 illustrate convincingly the extent of the increase in size produced in the sound field. The production of highly aggregated particles by our acoustical method is very rapidly brought about. The application of this method to a comprehensive study of the structure of aggregated particles might perhaps be convenient.

### Theoretical Discussion.

The effect of a sound field on suspended particles was first studied by W. König.<sup>10</sup> The work of König was continued with great success by Andrade.<sup>4</sup> S. W. Gorbatschew and A. B. Severny<sup>11</sup> have recently sought to discuss the forces in a sound field which may produce an aggregation of the suspended particles.

A comprehensive theoretical discussion of the process will be given shortly by the authors in another paper. Their theoretical calculations are partly based on the results of König and Andrade and partly on new considerations.<sup>12</sup> It will only be briefly outlined here.

For particles oscillating in a stationary wave the elongation  $x_{\text{mom}}$  is given by :

$$x_{\text{mom}} = A \sin \frac{2\pi a}{\lambda} \cdot \sin \omega t \quad . \quad . \quad . \quad (4)$$

where  $a$  represents the distance of the particle from the node,  $\lambda$  the wave-length of the sound waves,  $\omega/2\pi = n$  the frequency of the oscillations, and  $A$  the amplitude of the particles at the antinode.

The difference between the velocity of the gas particles and the suspended particles, is not great so long as the particles take part in the oscillation. The Stokes' formula may therefore be used to calculate the force operating at any moment on a particle :

$$K = 6\pi r \cdot \eta \cdot \Delta v \quad . \quad . \quad . \quad (5)$$

where  $\eta$  represents the coefficient of viscosity of the gas,  $r$  the radius of the suspended particle, and  $\Delta v$  the difference between the velocity of a suspended particle and that of a particle of the gas. From equations (4) and (5) one gets the differential equation :

$$m \cdot \ddot{x} = 6\pi r \eta \left( A \cdot \omega \sin \frac{2\pi a}{\lambda} \cdot \cos \omega t - \dot{x} \right) \quad . \quad . \quad . \quad (6)$$

The solution of this equation for the stationary case is given by

$$x = \frac{A \cdot \sin \frac{2\pi a}{\lambda} \cdot \sin (\omega t - \phi)}{\sqrt{\left( \frac{4\pi d \cdot r^2 \cdot n}{9\eta} \right)^2 + 1}} \quad . \quad . \quad . \quad (7)$$

<sup>10</sup> W. König, *Ann. Physik*, 1891, **42**, 353 and 549; **43**, 43; *Z. physik. chem. Unterr.*, 1895, **8**, 193.

<sup>11</sup> S. W. Gorbatschew and A. B. Severny, *Kolloid. Z.*, 1935, **73**, 146.

<sup>12</sup> O. Brandt and H. Freund, *Z. Physik*, 1935, **94**, 352, see footnote.

in which  $d$  is the density of the particles. The ratio of the amplitude  $X$  of the suspended particle to the amplitude  $G$  of a particle of the gas is given by :

$$\frac{X}{G} = \frac{1}{\sqrt{\left(\frac{4\pi d r^2 \cdot n}{9 \cdot \eta}\right)^2 + 1}} \quad (8)$$

Equation (8) may also be easily derived from the well-known formula given by König<sup>10</sup> by simplifying some expressions in that formula. The simple equation (8) is no less valid than the formula of König but it is much more convenient to handle. It is at once seen from equation (8) that for constant values of  $d$  and  $\eta$  the ratio  $X/G$  of the amplitudes is determined by the value of  $r^2 \cdot n$ . If the ratio  $X/G$  has a definite value the product  $r^2 \cdot n$  has also a definite value which may be calculated by equation (8). In other words a given ratio  $X/G$  and a given radius of the particles always correspond with a definite frequency  $n$ . The product  $r^2 \cdot n$  is therefore a critical relation with regard to the behaviour of the particle in the sound field.

In view of the aniso-dispersity of the aerosol it follows from this critical relation that (for the various suspended particles of the size usually present in aerosols) there always will be found a frequency between 5 and 50 k.c., where suspended particles of different sizes will also have different amplitudes. The difference will become greatest if part of the particles has already been increased by aggregation.

The differences in the amplitudes of the oscillating suspended particles occurring at these frequencies due to the aniso-dispersity of the system may cause the oscillating particles to collide in another and far more efficient way than that considered by Gorbatschew and Severny, who did not take into account the importance of the aniso-dispersity. Calculation of the efficiency of this effect shows that an appreciable amount of aggregation, due solely to these collisions, will occur only at high stages of concentration. Not only are the direct collisions of the particles efficient, however, but even the approach of the particles to one another is of importance, since it increases the probability of aggregation due to other effects. Quantitative calculations of the effect due to this approach of the particles are not yet possible.

The hydrodynamical forces of attraction as considered already by König must also be taken into account. It appears that importance must be attached to the observations of Andrade on vortex formation among particles which do not or only partially take part in the oscillation. Quantitative calculations as to the efficiency of vortex formation have also not yet been made.

The effect of the forces of attraction connected with the pulsation of spheres (studied by Bjerkness) has been considered in the paper of Gorbatschew and Severny. This effect is evidently of less importance with regard to the process of rapid coagulation since dry aerosols, in which no pulsation or a virtual pulsation will take place, may also be precipitated.

### High Frequencies.

The above-mentioned experiments were made with frequencies between 5 and 50 k.c., mainly between 10 and 20 k.c. At frequencies of some hundreds of kilocycles precipitation of smoke can also be observed

as was first reported by E. B. Pearson.<sup>18</sup> The phenomena occurring at the high ultrasonic frequencies cannot be directly compared with those at the frequencies of rapid coagulation. One essential difference is the fact that at these high frequencies not all the particles oscillate; under certain conditions no coagulation occurs at all. Several particles rotate around another without colliding. Fig. 14 shows the experimental arrangement. *Q* is the piezo-electric crystal, *R* is the horizontal sounding tube, and *M* the microscope. If the microscope is focussed on a layer just above the bottom of the tube the rotating particles can be readily observed as they do not disappear from the range of vision by sedimentation, but move only in a horizontal direction towards the nodes. They appear to be kept at this distance from the bottom by vortices (they disappear at once on disconnecting the ultrasonic generator). The

FIG. 14.—Ultrasonic arrangement.

particles moving to the nodes settle down there; these particles are very small compared with those formed by the process of rapid coagulation. Because of these and other effects the problem of aggregation produced by ultrasonic waves of high frequency needs still further investigation before it seems advisable to communicate any definite results.

### Summary.

The process of rapid coagulation by sonic and supersonic waves at frequencies between 5 and 50 k.c. is studied. Photomicrographic and kinematographic observations prove that the process of aggregation takes place in the sound field itself, and give suggestive information about the effect of the sound on the disperse system.

The enlargement of the particles was measured by two different methods. The results show that the particles may easily increase in size more than a hundredfold under the influence of the sound field.

Flowing aerosols may very efficiently be coagulated and precipitated if sufficiently large sound intensities are used.

No complete theory of the process can yet be given, as some of the complex factors cannot yet be calculated quantitatively. It could be deduced that the aniso-dispersity of the system must be taken into account when discussing the process.

# THE COAGULATION OF SMOKE BY SUPERSONIC VIBRATIONS.

By E. N. DA C. ANDRADE, D.Sc., Ph.D., F.R.S.

*Received 26th February, 1936.*

In a paper concerning the behaviour of particles in a column of vibrating air<sup>1</sup> I drew attention to the fact that smoke particles in air vibrating at supersonic frequencies would behave much like smoke or other dust particles in air vibrating at sonic frequencies.<sup>2</sup> Later E. B. Pearson, working in my laboratory, carried out some experiments on the subject,<sup>3</sup> and observed a rapid coagulation of tobacco smoke in air subjected to supersonic vibrations ranging from 92 to 801 kc./sec. He found that the coagulated particles formed double lines on the walls of the tube in the neighbourhood of the nodes, reminiscent of the heaps of dust which form to either side of the nodes in the familiar Kundt's tube experiment, and he was able to measure the velocity of sound at supersonic frequencies by means of these nodal figures. Mr. R. C. Parker, who is continuing such experiments, has obtained the phenomenon in a particularly clear manner, as illustrated in Fig. 1, which shows the rings obtained with magnesium oxide smoke at a frequency of 220 kc./sec.

It seems worth while to examine the theoretical aspect of the coagulation. Spheres at rest in a vibrating medium repel one another if their line of centres is parallel to the vibration vector, but attract one another if the line of centres is normal to this direction.<sup>4</sup> The force of attraction or repulsion varies inversely as the fourth power of the distance, and directly as the square of the (maximum) velocity of the vibrating fluid. This attraction of particles suitably placed is sufficient to account in a general way for the coagulation.

The calculations which lead to the results just quoted make many assumptions. In the first place, that the particles are at rest in the fluid, which certainly does not hold with the smallest particles. For instance, at 300,000  $\sim$ , for smoke particles, of density  $\rho = 1$  and radius  $r = 5 \times 10^{-5}$  cm., the ratio  $w_0/v_0$  is 0.182, where  $w_0$  is the velocity amplitude of the sphere and  $v_0$  that of the surrounding air, while for smaller and lighter particles  $w_0/v_0$  will be greater. For the purposes of obtaining an average value of the force for all particles it will, however, suffice to consider the particles as fixed if we take for the maximum velocity of the vibrating air the relative velocity  $v_0 - w_0$ , in place of  $v_0$ . A more serious point is that the calculations assume that the motion of the air surrounding the spheres is vortex-free, whereas under certain conditions, which ordinarily prevail in, for instance, a Kundt's tube, each particle is surrounded by a vortex system which governs the forces between the

<sup>1</sup> *Proc. Roy. Soc.*, 1931, 131A, 445, referred to in the present paper as "Circulations."

particles.<sup>5</sup> The general explanation of the coagulation is not vitiated even if vortex systems are found, for two particles with transverse lines of centres are still attracted, but the law of force has not been worked out in the case of vortex motion, so that, if it takes place, no attempt at a quantitative theory can be made.

Let us first examine if the assumptions of vortex-free motion can be supported in the case of ordinary smokes. It has been shown<sup>6</sup> that for small spheres the conditions which govern the initiation of vortex motion are expressed by

$$\frac{nad}{\nu} > 4.6$$

where  $n = 2\pi f$ ,  $f$  being the frequency of the vibration:  $d$  is the diameter of the sphere:  $a$  the amplitude of the air vibration:  $\nu$  the kinematic viscosity of the medium. The smallest spheres for which this law was proved were 0.25 mm. in diameter, and the greatest value of  $n$  was 7540, so that in extending it to the supersonic case we are extrapolating beyond our experimental range. There are, however, theoretical reasons for

supposing that this extension is justified. The value of  $\frac{1}{d}\sqrt{2\nu/n}$ , is not very different in the experiments in question and in the supersonic case, and it is apparently only large differences in this quantity, and then in a direction other than that which holds in the present case, that render the extrapolation invalid.<sup>7</sup>

If  $f = 100$  kc./sec. and the value of  $\nu$  be taken as 0.15 (air), then formula (1) gives  $ad > 1.1 \times 10^{-6}$ : if  $f = 800$  kc./sec.,  $ad > 1.3 \times 10^{-7}$ .

If therefore  $d < \frac{1.3 \times 10^{-7}}{a}$  we need not anticipate vortex motion even at 800 kc./sec., while even for  $d < \frac{1.1 \times 10^{-6}}{a}$  we are safe at 100 kc./sec.

We can make a rough estimate of the greatest value of  $a$  from the breaking strength of quartz crystals. Taking this as  $9 \times 10^{10}$  dyne/cm. (given as maximum value in *International Critical Tables*, 4, 22) we get for the maximum velocity at the crystal face 700 cm./sec., which at  $f = 800$  kc./sec. gives an amplitude of  $1.4 \times 10^{-4}$  cm., and at  $f = 100$  kc./sec. gives  $1.1 \times 10^{-3}$  cm. Owing to resonance these values will be exceeded in the air column, but against this the crystal is never run near amplitudes that lead to fracture normal to the axis. If we take these figures as giving roughly the amplitude of the air vibration, we see that we shall not get vortex motion unless  $d > 10^{-3}$  cm. Another factor that will tend to suppress vortex motion with smaller particles is that as the particles get smaller the *relative* velocity of air and particle decreases.

We are justified, then, in assuming vortex-free motion. In this case the force between two spheres each of radius  $r$ , at distance  $d$  from one another, is given by

$$\left. \begin{aligned} X &= -\frac{3}{2} \frac{\pi \rho r^6 \omega_0^2}{d^4} \sin \theta (1 - 5 \cos^2 \theta) \\ Y &= 0 \\ Z &= -\frac{3}{2} \frac{\pi \rho r^6 \omega_0^2}{d^4} \cos \theta (3 - 5 \cos^2 \theta) \end{aligned} \right\} \quad . \quad . \quad (1)$$

<sup>5</sup> *Circulations*, p. 454, *et seq.*

<sup>6</sup> *Ibid.*, p. 463 *et seq.*

<sup>7</sup> *Ibid.*, p. 467.

where  $\theta$  is the angle which the line of centres makes with the direction of the vibration velocity  $W$ . The force is thus proportional to  $\frac{r^6 w_0^2}{d^4}$ .

The repulsion which takes place when the line of centres of the particles approaches the direction of the vibration vector need not concern us, as the only effect which it can have on coagulation is a secondary one.

Two particles of the size contemplated, moving together under an attractive force of the magnitude in question, can, in a viscous medium such as air, be supposed to move at a speed proportional to the force and inversely as the surface. The assumption that the resistance is proportional to  $r^2$  is, of course, a provisional one, as the problem of a sphere moving through a liquid oscillating at right angles to the motion has not been solved, to my knowledge. For a sphere simply oscillating in a viscous liquid, however, the component of the resistance which assumes importance for our frequencies and linear dimensions ( $n = 2 \times 200$  kc. per sec.,  $a = 10^{-4}$  to  $10^{-5}$  cm.) is proportional to  $r^2$ . The oscillations in our case are, of course, transverse to the travel. The consideration of the accelerated motion of a sphere through the liquid is very complicated, involving as it does  $\frac{dv}{dt}$  and terms in  $r^3$ ,  $r^2$  and  $r$ . The selection here made of  $r^2$  is justified by the fact that measurements by Mr. Parker, carried out after the calculation had been completed on this basis, agree very well with the formula deduced.

On this assumption the time taken for the particles, of fixed radius  $r$ , to move from a distance  $d$  until they are in contact, at distance  $2r$  between centres, is

$$t = K' \int_{2r}^d x^4 dx = K(d^5 - 32r^5)$$

$K$  is a constant during the movement of the particles up to the time when they touch and adhere, but is inversely proportional to  $r^4 w_0^2$ . Let  $M$  = mass of smoke per c.c., whatever the concentration, so that we are dealing with the coagulation before an appreciable amount of smoke has settled, and  $N$  the number of particles at any moment.

Then mass of single particles  $= \frac{M}{N} = \frac{4}{3} \pi r^3 \rho$

$$\therefore r = AN^{-\frac{1}{3}}$$

where

$$A = \left( \frac{3M}{4\pi\rho} \right)^{\frac{1}{3}} \quad (2)$$

The average distance between the particles  $= d = N^{-\frac{1}{3}}$ . The relative velocity of air and particle, in the case where the particles are not so heavy as to remain fixed while the air washes over them, is

$$v = \left( \frac{1 - w_0}{v_0} \right) r_0$$

where  $w_0$  is the maximum velocity of the particle during vibration, and  $v_0$  that of the air.

Hence  $\tau$  = time in which number  $N$  of particles is halved,

$$\begin{aligned} &= BN^{\frac{1}{2}} \frac{1}{v_0^2} \left(1 - \frac{w_0}{v_0}\right)^{-2} (N^{\frac{1}{2}} - 32A^{\frac{1}{2}}N^{\frac{1}{4}}) \\ &= BN^{\frac{1}{2}} \frac{1}{v_0^2} \frac{1}{\left(1 - \frac{w_0}{v_0}\right)^2} (1 - 32A^{\frac{1}{2}}) \\ &= PN^{\frac{1}{2}} \left(1 - \frac{w_0}{v_0}\right)^{-2} \quad \dots \dots \dots (3) \end{aligned}$$

where  $P$  is constant for a given mass of smoke and velocity-amplitude of the air.

Let us suppose that, at the frequency concerned, even the smallest particles with which we deal are not appreciably entrained, i.e.,  $w_0/v_0$  is negligible. Then, considering the process as a continuous one

$$- \frac{dN}{N} = C'N^{\frac{1}{2}} dt$$

or

$$\begin{aligned} dt &= -C'N^{\frac{1}{2}} dN \\ t &= C(N_0^{\frac{1}{2}} - N^{\frac{1}{2}}) \quad \dots \dots \dots (4) \end{aligned}$$

which gives an initially rapid falling off of number of particles with time, becoming slower as time increases. Fig. 1 represents this law.

Formula (4) gives a coagulation rate which is independent of frequency, because  $w_0/v_0$  has been taken as zero (particles at rest in oscillating medium). Actually, however,  $w_0/v_0$  while exceedingly small for very high frequencies, approaches unity as the frequency diminishes, and it is this that makes rate of coagulation increase with frequency. The factor  $w_0/v_0$  is also a function of the particle size, decreasing as the particle size increases, so that for lower frequencies, where  $w_0/v_0$  is initially not negligible, the curve of Fig. 1 gives a rate of coagulation that is too rapid in the initial stages as compared with the later stages. The quantitative relation is given by the somewhat complicated formula \*

$$\frac{w_0}{v_0} = \frac{\left\{ \frac{1}{a^2} + \frac{3b}{a} + \frac{9}{2b^2} + \frac{9}{2b^3} + \frac{9}{4b^4} \right\}^{\frac{1}{2}}}{\left\{ a^2 + 3ab + \frac{9}{2}b^2 + \frac{9}{2}b^3 + \frac{9}{4}b^4 \right\}^{\frac{1}{2}}} \quad \dots \dots \dots (5)$$

Here  $a = \frac{2\sigma + 1}{3}$ , where  $\sigma$  is the ratio of the density of the particles to

that of the medium, while  $b = \frac{1}{r} \sqrt{\frac{\nu}{\pi n}}$ . For instance with particles of magnesium oxide ( $\rho \doteq 0.35$ ) in air,  $a = 200$ ; with tobacco smoke  $a = 820$ . With air

$$b = 0.087 \frac{1}{rf^{\frac{1}{2}}} = \frac{0.087}{A} \frac{N^{\frac{1}{2}}}{f^{\frac{1}{2}}} = B \frac{N^{\frac{1}{2}}}{f^{\frac{1}{2}}} \quad \dots \dots \dots (6)$$

In any particular case, therefore, we can find the value of  $B$ , and, substituting in (5), obtain  $w_0/v_0$  as a determined function of  $N$  and  $f$ . If we substitute this in (3) we have a relation between  $\tau$  and  $N$  which involves  $f$  and known constants only.

Equation (5) can be simplified only in certain cases, which are best considered as they arise, that is, when particular experiments, with known

\* W. König, *Ann. Physik*, 1891, 42, 353. See also E. N. da C. Andrade, *Proc. Roy. Soc.*, 1935, 134A, 445.

values of  $B$ , are in question. It may, however, be pointed out that if  $M = 3 \times 10^{-7}$  gm./cm.<sup>3</sup>, which gives, from (2) and (6),  $B = 14.8$  with  $\rho = 0.35$ :  $r = 5 \times 10^{-5}$  cm. initially:  $f = 300,000$ : then, in (6),  $b = 3.2$ , and we can neglect  $9/2 b^2 + 9/4 b^4$  in comparison with  $a^2 + 3ab$ , as amounting to about 1 per cent., and decreasing as coagulation takes place. We can then use the simplified expression

$$\left(1 - \frac{w_0}{v_0}\right)^2 = \frac{\{(a^2 + 3ab)^{\frac{1}{2}} - \frac{3}{2}b(2b + b^2)^{\frac{1}{2}}\}^2}{a^2 + 3ab}.$$

In general, however, further simplification is not possible, owing to the values of  $b$  being neither small nor great compared to 1.

As an example we may take the following figures, where  $(w_0/v_0)_0$ ,  $(w_0/v_0)_{.5}$ , and  $(w_0/v_0)_{.1}$ , represent the initial value and the values after the number of particles has been reduced to one-half and one-tenth respectively. The initial radius  $r$  is taken as  $5 \times 10^{-5}$  cm.

$f$ .	$(w_0/v_0)_0$ .	$(w_0/v_0)_{.5}$ .	$(w_0/v_0)_{.1}$ .
300,000	0.01	negligibly small	
75,000	0.111	0.050	0.008

This shows that at  $f = 300,000$ , Fig. 1 should represent the state of affairs without correction. At  $f = 75,000$  the initial rate is

$$(1 - w_0/v_0)^2 = 0.79 \text{ times,}$$

and the rate after  $N$  has been reduced to a half is 0.90 times, the value given by Fig. 1, the rates for values of  $N$  less than  $0.1 N_0$  being appreciably the same.

Since this paper was first communicated to the Society Mr. Parker has carried out experiments which have confirmed formula (4), and so substantiated the general correctness of the theory.

## EXPERIMENTS ON COAGULATION BY SUPER-SONIC VIBRATIONS.

BY R. C. PARKER, B.Sc.

*Received 7th April, 1936.*

Professor E. N. da C. Andrade suggested to me that I should look into the question of the coagulation of smoke by supersonic vibration experimentally, with the object of seeing how far the formula which he has derived actually represents the variation of the number of particles with time. The experiment has been carried out with magnesium oxide smoke in air, vibrating at a frequency of 220 kc./sec. In the method used the vibration is allowed to continue for a given time, and the concentration is then determined. The natural coagulation during the period of measurement is negligible, and it has been found possible to reproduce a standard initial concentration with great consistency.

The particle concentration was determined in a manner similar to that employed by Perrin for counting particles in a dilute colloidal solution in his experiments on Brownian motion. The freely suspended particles were viewed through an ultramicroscope fitted with a Zeiss 23.5 mm. achromatic objective, the number visible being that contained in a volume equal to the product of a prescribed area of the field of view and the depth of focus

FIG. 1.

rotation. It was found necessary to eliminate any motion of the particles that might arise from convection, otherwise the number of particles seen in the field of view would depend upon their velocity. The several precautions adopted to minimise this source of error are detailed in a forthcoming paper by Andrade and Parker; they are chiefly concerned with the method of insulating the tube against any local temperature variations, and ensuring that its temperature is that of the entering smoke-laden air.

The magnesium oxide smoke was obtained by burning 9.7 mgm. of magnesium ribbon in a stone jar of 12 cubic litres capacity. A diagram of the arrangement used is shown in Fig. 1. A brass cap C, which served to support two long electrodes, fitted closely over an opening in a metallic plate, cemented so as to close the jar. To the lower electrode was fixed an asbestos covered cup on which was placed the requisite amount of magnesium ribbon. Connected across the electrodes, and in close contact with the magnesium ribbon, was a length of resistance wire. The mag-

of the optical system. In the eyepiece ( $\times 12.5$ ) was inserted a chess-board graticule which enabled the field of view to be restricted within known limits, according to the type of graticule used and the number of squares considered. The concentration was then ascertained by noting the number of particles which could be seen instantaneously in a known volume. A photographic shutter, placed in the path of the illuminating beam, was opened every two seconds for the duration of half a second, and the number of particles noted at each exposure. This number never exceeded 7 or 8. The final values given below (Table II.) represent, for each concentration, the mean of about 720 counts and have a probable error of less than 1 per cent. Only 120 counts were made for any one given filling, after which time the contents of the tube were renewed and the air was set into vibration for the requisite period. Owing to the steady condition of the smoke any local irregularities in its distribution tended to persist over several counts, and hence a more representative value was obtained by selecting for observation each graticule square in

FIG. 2.

netic ribbon, was a length of resistance wire. The mag-

nesium ribbon was ignited by passing a current through the resistance wire, and filled the jar with smoke. To determine whether this process gave reproducible results it was repeated six times, the initial smoke concentration being each time ascertained by counting. The values obtained

by two observers making 360 counts, are detailed in Table I., and, as may be seen, their mean values obtained by the two observers agree to within 1 per cent. To make certain that, in the absence of a sound field, the normal coagulation and settling under gravity was small, observations were extended over eight minutes, there being exhibited, during this time, no fall in the concentration.

The smoke, on which the above observations were made, was contained in a glass tube of length 10.5 cm and internal diameter 2 cm. One end of the tube was closed by a flat glass disc, while the other end was closed by a cylindrical quartz crystal oscillator which fitted with a small clearance all round. Fig. 2 is a cross-section through the tube at the point, 6 cm. from the oscillator, where the observations were made. The holes A and B were closed by windows of very thin

FIG. 3.

glass (the iridescent fragments of a quickly blown bulb) smoothly stuck to the inner surface of the tube, care being taken to avoid any projection which might cause vortex motion. A pointolite lamp, in conjunction with

a convenient optical system, was employed to illuminate the field of view, and a water cell, 12 inches long, containing a solution of cuprous ammonium sulphate eliminated any heating effect which the beam might have.

The values for the particle concentration were obtained for 8 values of  $t$ , the time during which the supersonic vibrations were maintained. The greatest value of  $t$  was eight minutes, which caused the number of particles to fall to about  $1/40$ th of the initial value. The eyepiece graticule chosen for the lowest concentration gave an area of observation 16 times

that used at the highest concentration. Unit volume was taken as that bounded by the graticule square of smallest area, as used in determining the initial concentration. At the very low concentrations, i.e., when the time interval was six to eight minutes, there was a tendency to include certain small non-coagulated particles which were present, and were more obvious when, as occasionally happened, there were no coagulated particles in the field of view. The observations were divided between two observers, whose estimates were in good agreement. As there was usually a number of particles visible, that were not in focus, a certain amount of practice was found necessary: then, ultimately, very satisfactory consistency was obtained.

Table II. gives the values obtained for various times of the coagulating vibration, each value in the fourth column being the mean of about 700 counts. In Fig. 3 is drawn the theoretical relation between the concentration and time, the points plotted being those experimentally determined. The resulting agreement is, as may be seen, extremely close, and there can be little doubt that the mechanism considered in the theoretical treatment closely corresponds to the existing conditions. Too much reliance must not be placed upon the slight deviation shown at low concentrations, for it is there that the experimental observations become less consistent.

### GENERAL DISCUSSION.\*

**Dr. E. G. Richardson** (*Newcastle*) said: The authors have established that there is a range of frequency in the supersonic region most effective for coagulation; is there not also a most effective amplitude range? Mr. T. Laidler and I, at Newcastle, measuring the velocity of sound in aerosols, found that coagulation may be to a large extent inhibited, even when using a supersonic source, if the amplitude is kept to a minimum. On the other hand, a large amplitude is known to favour dispersion, as in the production of emulsions by supersonics.

Brandt and Hiedemann have used optical absorption to measure the change of particle size during coagulation, citing the work of Wiener as justification for the assumption that the absorption of light is proportional to the square of the particle diameter. Though this method is very precise, yet I think the results they have obtained from it require correction. Wiener was concerned with transparent particles, i.e., fogs. I have verified the same law for the extinction of light by opaque particles in suspension down to  $10\mu$ , yet for diameters between  $10\mu$  and  $1\mu$  Cheveneau and Audubert<sup>1</sup> have shown that an extinction coefficient proportional to the diameter fits the results better. What was the range of particle size in the present experiments?

**Mr. G. W. Slack** (*Leeds*) said: it may be questioned whether any differentiation, in the later stages of coagulation, between coagulated and uncoagulated particles is desirable in what is fundamentally a statistical investigation, since any such distinction must obviously be made on an arbitrary size-basis and since, moreover, it is impossible to say at what time this process should be started. If we count *only coagulated particles* then the number at the start must be taken as zero, whilst on the other hand if we count *all* the particles, then, towards the end, Mr. Parker's counts are admittedly too low and the divergence from the theoretical expression of Professor Andrade will be in the same direction as the results of Brandt and Hiedemann,<sup>2</sup> and also in accordance with the qualitative experiments of Patterson and Cawood<sup>3</sup> who found a distinct tendency for small particles to persist after the major portion had flocculated out.

From the paper it is not clear that the smoke must have been diluted, or otherwise treated in some way, to reduce the number of particles, since on making a cloud of the mass concentration given the numbers fell rapidly from  $5 \times 10^7$  to  $5 \times 10^6$  in  $6\frac{1}{2}$  mins.

**Dr. K. Söllner** (*London*) said: Liquid, non-metallic substances are dispersed into gases by the same mechanism as that which causes emulsification in liquid/liquid systems, i.e. cavitation, as was shown a short time ago.<sup>4</sup> When the sound travels through the liquid, the latter is stretched locally and disrupts there, forming a cavity. If an external force (e.g. gas pressure) acts from outside this cavity collapses vehemently, as was shown by Lord Rayleigh.

<sup>4</sup> C. Bondy and K. Söllner, *Trans. Faraday Soc.*, 1935, 31, 835.

Attention should be drawn also to the papers on orthokinetic coagulation by G. Wiegner and co-workers, chiefly Tuorila,<sup>6</sup> who have developed a theory, which takes into account the different velocities of particles of different size, when an external force acts upon the whole system, e.g. the different rate of sedimentation in a suspension of particles of different size causes collisions between these particles, thus increasing the rate of coagulation. This orthokinetic coagulation was very helpful in understanding the coagulation of emulsions by ultrasonics,<sup>6</sup> and it may be applied profitably also to gaseous systems.

**Mr. A. G. Grant** (*Darlington*) said: These very interesting papers on particle coagulation by sonic and supersonic means, open up a wide field of speculation. At the present time there are many simple means of removing coarser particles from gases, and it is the fine particles which introduce complexity and expense. I wonder if sonic coagulation will prove capable of large scale application as a preliminary to electrical precipitation or other known means of particle extraction.

**Dr. R. Lessing** (*London*) said that Mr. Grant's suggestion that the primary aggregation of particles by supersonic waves might form a first step in the industrial elimination of dispersoids from gases, had an analogue in the addition of flocculating agents to suspensions, which had in recent years been introduced into sedimentation and clarification practice.

**Professor R. Whytlaw-Gray** (*Leeds*) said: Has Dr. Hiedemann any evidence on the electrical state of the particles during supersonic coagulation? They may possibly become electrified. Has anything suggesting this been observed?

The photographs in Dr. Hiedemann's paper of the aggregates precipitated by this process exhibit the same structures on a larger scale as those formed in the much slower process of natural coagulation.

**Dr. E. Hiedemann** (*Köln*) said: We do not agree with Andrade when he attributes the cause of acoustic coagulation only to the forces between spheres in an oscillating medium, as comprehensively studied by Bjerkness.<sup>7</sup> A direct comparison of our results and those obtained by Andrade cannot be made, as the experimental conditions were very different. At the high frequencies he used, the suspended particles do not, in effect, oscillate, whereas at the lower frequencies most of the as yet unaggregated particles oscillate. The conditions at the lower frequencies are much more complicated, as we have seen from our theoretical calculations and our experimental results. The order of magnitude of the effect of the sound field is also quite different. The process of supersonic precipitation studied by Andrade and co-workers takes some minutes to complete, whereas the rapid coagulation by sonic and supersonic waves studied in our experiments needs only a few seconds or less. I will therefore only point out some theoretical points with regard to Andrade's interesting theory. His equation (1) was derived by W. König,<sup>8</sup> who used simplifying assumptions. It is difficult to judge whether these simplifying assumptions are justifiable at the very high frequencies he used, especially where the particle size is so small that molecular discontinuity cannot be neglected for precise quantitative calculations. To approach a solution of the problem it is, of course, justifiable to start with such simplifying assumptions; for this reason we have also used König's formula in calculating<sup>9</sup> the order of magnitude of the Bjerkness' forces of attraction in the process of coagulation. We preferred to assume the force of the resistance of the medium to the approaching particles to be proportional to  $r$ , whereas Andrade has chosen  $r^2$ . The law of resistance

<sup>10</sup> O. Brandt, *Dissert.*, Köln., Feb., 1936.

for particles moving at right angles to the oscillation of the medium is as yet unknown, but if one assumes that the motion of particles towards one another is independent of the oscillation of the medium at right angles to that motion, the resistance must be assumed to be proportional to  $r$  until somewhat large particle velocities are obtained. If one considers particles of diameter  $1\mu$ , Reynolds' number is smaller than 0.2, so long as the velocity of the particles is smaller than 600 cm./sec.

The anisodispersity of the system is another serious difficulty, especially as we have seen from our measurements that incipient aggregation has the effect of rendering the system still more anisodisperse. One would also conclude from Andrade's equation (1) that the largest particles coagulate first as the forces of attraction are proportional to  $r^6$ , and this would also have the result of making the system more anisodisperse.

In consequence of the large increase in mass of the particles, one would expect an accelerated sedimentation, *e.g.* similar to that shown in Fig. 1 of the paper. Could the mass-concentration  $M$  in equation (2) be made constant?

Notwithstanding these difficulties, the agreement between Andrade's and Parker's experiments is excellent. But even this cannot suppress another serious doubt. The calculations are made for particles of a strictly spherical shape, but the experiments were made with magnesium oxide smoke. Even if one could assume the primary particles to have an approximately spherical shape, one must consider that after the first aggregation of two particles the enlarged particles are not spherical at all; for increased coagulation the structure will be very flocculent.

Although one approaches with diffidence the simplifying assumptions of Andrade's theory, the agreement between the theory and the experimental results is so remarkable that one may hope to obtain reliable knowledge of the forces causing aggregation at high supersonic frequencies.

**Mr. R. C. Parker** (*London*) in reply, said: The distinction made between the coagulated and uncoagulated particles did not play the important part in the observations which Mr. Slack suggests. A few small non-coagulated particles were observed at all stages, and were clearly very different in size, as judged by their brightness, from the main body of particles. After 6 or 8 minutes, when the coagulated particles were very scarce, the smaller particles were comparable in number with the now very much larger particles which were counted. From the point of view of the problem under consideration the uncoagulated particles should clearly not be taken into account. What is in question is not the number of particles, but the number of effective unions, a large number of which go to the making of one larger particle. That the distinction made was not an arbitrary one is clearly shown by the fact that two independent observers, working without any possibility of conscious or unconscious collusion, obtained consistent results.

Mr. Slack has, later, confounded the concentration in the stone jar, in which the smoke was originally produced, with that existing in the observation chamber. The smoke produced in the stone jar was highly concentrated and coagulated rapidly, as would be expected from the work of Whytlaw-Grey and his collaborators. After standing for some minutes, however, the smoke was passed through several pipes and a calcium chloride drying tube, where further coagulation and filtration took place. The result was that the smoke, as initially observed in the observation chamber, had a concentration of  $10^8$  particles per cm.<sup>3</sup>, which did not diminish appreciably in the time concerned. Extremely slow coagulation at this concentration would be anticipated from the work of the Leeds school.

**Professor E. N. da C. Andrade** (*London*), in reply to Dr. Richardson, said: The variation of coagulation with amplitude is a point of great importance, which has not yet been investigated. According to my ideas the rate of coagulation should vary as the square of the amplitude, and measurements directed to this point would throw valuable light on the

mechanism. No experiments, however, have yet been made in this direction in my laboratory.

As regards the very interesting paper by Brandt and Hiedemann, it is to be regretted that fuller information is not given. We are not told the frequencies which were used, nor, in particular, what precautions were taken against convection, which is generally found troublesome, but which we have eventually succeeded in eliminating. Since, in Fig. 4, the sound was cut off for photographs (*g*) and (*h*), and all the streaks are in the same direction, it would appear that convection is largely responsible for the nature of the images. There seems to be no influence that could orient actual long particles all in the same direction. I am also not clear why the exposure was lengthened from  $1/125$  second for Fig. 3*a*, to  $1/10$  second for Fig. 3*b*. The longer exposure may play some part in the changed appearance. I am a little troubled as to why tobacco smoke particles, which are practically all water, are called dry.

The sketch of the theory is hardly full enough to justify critical consideration. I may say that, for sonic frequencies, I have found, with the assistance of Mr. R. A. Scott, that at  $2300 \sim$ , with an amplitude of  $0.15$  mm., coagulation of tobacco smoke takes place rapidly, (tube practically clear of smoke in 1 minute) whereas at  $165 \sim$ , and an amplitude of  $1.5$  mm., there was no appreciable coagulation due to the sound in half an hour, although the concentration was fairly high. If the forces which I have assumed active in my theory are really responsible for the coagulation this is easily explained, since at  $2300 \sim$  there will be a small relative motion between the air and smoke particles, while at  $165 \sim$  there will be practically none. With the very much greater amplitude which prevails at  $2300 \sim$  than in the supersonic case, a relative motion amounting to only a small fraction of the total amplitude should be sufficient to produce marked coagulation. It is quite possible that these experiments at sonic frequencies are also explicable in general terms on the theory of Brandt and Hiedemann, since at low frequencies all particles, small and great, have about the same amplitude. I am, however, in some doubt as to how their theory can explain the results at high supersonic frequencies, where all particles, small and great, are at rest in the medium. I do not think, therefore, that the aniso-dispersity, which on their theory is responsible for the coagulation, can play any part in the supersonic case, although, of course, both it and the hydrodynamic forces may be active at sonic frequencies. Further experiment is needed on this point.

As regards the criticism of my theory, what is required to test a theory is some kind of quantitative formula which can be experimentally checked, and in the case of a problem as complicated as the present one, some kind of simplifying assumptions are necessary. Those I have made are tentative rather than well established, and I am well aware that subsequent workers may improve upon them. They do, however, furnish some indication of how the problem can be approached. As regards the resistance proportional to  $r^2$ , the particle is not moving uniformly but rapidly accelerating, and I have given a rough reason for my adoption of this law. At any rate the application of Stokes' law is clearly not justified. I have actually tried the effect of a resistance proportional to  $r$ , and found a formula which disagrees violently with Mr. Parker's observations. This is in itself of some importance, as showing that the experimental results do not agree with practically every likely-looking formula, as might be the case.

I look forward to studying the full theory of Brandt and Hiedemann, especially in its bearing on the variation of rate of coagulation with frequency.

**Dr. E. Hiedemann (Köln)**, said: In reply to Dr. Richardson: We have not found a most effective range; we have as yet only observed that the process of rapid coagulation is the more effective the higher the amplitudes. Although large amplitudes of supersonic waves are known to favour dispersion in liquids, such an influence on suspended systems in gases has never been reported.

Our assumption that the absorption of light is proportional to the square of the particle diameter is based upon the work of O. Werner (*loc. cit.*) W. Trabert,<sup>10</sup> G. Mie (*loc. cit.*) and W. Findeisen.<sup>11</sup>

O. Werner has measured the dependence of the absorption of light in fogs upon the particle diameter when the mass-concentration remains constant. The evaluation of his experimental curves in some cases accords with the assumption that under these conditions the extinction of light is proportional to the reciprocal particle diameter, but in other cases the agreement is not good. The different results of Chénevau and Audubert were obtained with suspended particles in liquids and may perhaps not be valid for suspended particles in gases. Most of our particles had diameters from 1.6 to 2.0  $\mu$ . During the coagulation the diameters of the particles increase rapidly to more than 10  $\mu$ . Even though our assumption should not be quite justified for the smallest particles, only the very first part of the curve would require some correction. The uncertainty of this small and as yet not important part of the curve is unavoidable as different authors cited have got different results. Another and more important uncertainty is due to the aniso-dispersity of the system. But in the evaluation of our measurements both uncertainties may safely be neglected as we only sought information upon the order of magnitude.

In reply to Dr. Söllner: In the short outline of our theory of the process of rapid coagulation we have already mentioned that we have found the anisodispersity of the system to be of importance for the aggregation.<sup>12</sup> The different velocity-amplitudes of the particles of different sizes bring about kinetic impacts leading to coagulation in the frequency range used.

In reply to Mr. Grant: Measurements of the energy required for the process of rapid coagulation by sonic and ultrasonic waves have so far only been made with the usual laboratory apparatus. The efficiency of the apparatus depends of course very much on the sort of acoustic generator used. With a certain generator the efficiency of the sonic aggregation could well be compared with that of electrical precipitation. But the results of experiments on a small scale do not permit definite conclusions regarding large scale application, as one knows many cases in which a chemical process, which is very satisfactory in a test-tube, is quite discouraging when tried on a large scale. It will therefore only be possible to answer this question when comprehensive experimental work has been done on a large scale. We have undertaken such experiments, but some time must elapse before we can give reliable information as to large scale application.

In reply to Professor Whytlaw-Gray: In some cases we have indeed little doubt that the particles precipitated by the process of rapid acoustic coagulation were electrically charged. If, for example, a precipitated aggregate was divided by means of a sharp point, some of the divided aggregate had somewhat strong electric charges. If one moved such charged aggregate through the other aggregates without touching them, forces of attraction and of repulsion could easily be observed. As the experiments on the electric charge of the coagulated, but still suspended, particles are not yet concluded I cannot make any definite statements for this case.

As Professor Whytlaw-Gray points out the aggregates precipitated by the process of rapid acoustic coagulation do exhibit the same structure as those formed in the process of natural coagulation. Since the acoustically produced aggregates are much larger, microscopic study of them may perhaps help to complete the study of the shape of the naturally formed aggregates so successfully made by Professor Whytlaw-Gray and his co-workers.

<sup>10</sup> W. Trabert, *Meteor. Z.*, 1901, 18.

<sup>11</sup> W. Findeisen, *Dissertation*, Hamburg, 1931.

<sup>12</sup> O. Brandt and E. Hiedemann, *Kolloid-Z.*, 1936, 75, 129; O. Brandt, *Dissertation*, Köln, 1936.

**Mr. A. G. Grant** (*Darlington*) said: From the statements just given by Dr. Hiedemann it looks as if the power for sonic aggregation would be of the same order as that required for precipitation. In this case, as some form of removal plant would still be necessary, the merits of sonic aggregation as an industrial process will be determined entirely by the initial cost of the plant involved.

**Dr. E. Hiedemann** (*Köln*) said, in reply to Professor Andrade: The measurements and kinematographic observations given in our paper were made at a frequency of 10 k.c., though we have made other observations and measurements over the whole range of frequency of some k.c. to some hundred k.c. As the rapidity of the coagulation at 10 k.c. under our experimental conditions is enormous compared with that studied by Andrade and Parker, convection effects were absolutely negligible, so that we did not need to take any precautions against it. Professor Andrade has misunderstood Fig. 4. What he supposes to be actual long particles oriented all in the same direction are not pictures of particles but of the tracks of the coagulated particles when sedimenting. The tracks of falling particles are of course all in the same direction. From the description of our optical arrangement in Fig. 1 it will be seen that the observation was ultramicroscopic. The reason for choosing different times of exposures in Figs. 3a and 3b is stated in our paper so that this question appears also to be due to the misinterpretation.

In calling  $\text{NH}_4\text{Cl}$ - and tobacco smoke particles "dry" we, of course, only wanted to distinguish between really liquid particles (such as oil drops) and particles consisting of or containing solid or nearly solid matter. The nature of tobacco smoke particles is explained when describing Fig. 11. The opinion of Professor Andrade that tobacco smoke particles "are practically all water" has rather surprised me. Mr. E. B. Pearson working in his laboratory has used cigarette smoke.<sup>12</sup>

On page 139 he states that he has used "smoke, dried by being blown through a long calcium chloride tube." If it were true that smoke particles "are practically all water" I am at a loss to understand what remained in Mr. Pearson's smoke after drying it.

Our theory which is here given only in outline will shortly be published in full elsewhere. We will therefore not deal with the remarks on that outline but will only draw attention to some misunderstandings. We have said that the anisodispersity of the medium is an important factor in the process of coagulation at frequencies between some k.c. and about 50 k.c. (determined by the critical relation  $r^2 \propto n$ ). But we have not said that this alone is responsible for the coagulation. For the case of higher supersonic frequencies we have given no theory at all, as we want more experimental results before trying to do so. When I pointed out the importance of the anisodispersity of the medium for the case of higher supersonic frequencies I did not of course mean the coagulation effects due to the anisodispersity, which we treat in our theory and which would be called orthokinetic coagulation in the terminology of Wiegner and Tuorila, as Dr. Sollner has remarked. I directed attention to the fact that the forces of attraction in König's equation used by Professor Andrade are proportional to  $r^4$ . From this I would conclude that no theory which disregards the anisodispersity of the medium can be expected to give very reliable results. I cannot share the opinion of Professor Andrade as to the law of resistance and I shall treat this question very comprehensively in our forthcoming theory. I regret that Professor Andrade has not indicated how it was ensured that the mass-concentration in Mr. Parker's experiments remained constant.

Professor Andrade's chief objection to my serious doubts as to the reliability of his theory is the agreement between his quantitative formula and the experimental results obtained by Mr. Parker. Mr. Parker's

<sup>12</sup> *Proc. Physic. Soc.*, 1935, 47, 137.

curve indeed agrees remarkably well with  $\frac{dN}{dt}$  proportional to  $N^{2/3}$  but, I am troubled by the fact that this formula cannot be derived from Professor Andrade's theory. If one makes the same assumptions as Professor Andrade makes, one really obtains equation (3), but, as a mathematical consequence, one does not get the three next equations given by Professor Andrade. On the contrary mathematical calculations give the following equations :

$$\begin{aligned}-\frac{dN}{N} &= e' N^{1/3} dt \\ dt &= -e' N^{-4/3} dN \\ t &= e''(N_0^{-1/3} - N^{-1/3})\end{aligned}$$

and these equations mean that  $dN/dt$  is proportional to  $N^{4/3}$ . This formula violently disagrees with Mr. Parker's results. That Professor Andrade's quantitative formula is not correct can very easily be seen ; if, for instance,  $t$  could be calculated from equation (4), he would get  $t$  proportional to  $N^{4/3}$  instead of  $N^{-1/3}$ . However, I also regard the hydrodynamic forces as important in the case of higher supersonic frequencies.

## MEASUREMENT OF THE OPTICAL DENSITIES OF SMOKE STAINS ON FILTER PAPERS.

BY A. S. G. HILL.

*Received 9th March, 1936.*

Estimations of atmospheric pollution are made from stains obtained by drawing known volumes of the polluted air through a restricted area of filter paper. The object of the investigation described in this paper was to determine the suitability of employing a photo-electric density meter to obtain a measure of the optical density of these smoke stains, instead of the more usual visual comparative method involving the use of standard stains. It was desired to relate the stain optical density with the mass of the disperse phase in such stains, and so to estimate the smoke concentration.

### Method.

A photo-electric density meter, similar to that designed by F. C. Toy<sup>1</sup> was constructed by modifying the original selenium cell form of the instrument.<sup>2</sup> The selenium cell was replaced by a caesium gas-filled photo-electric cell, with valve amplification. The apparatus is shown diagrammatically in Fig. 1.

Two beams of light from opposite sides of a 6-volt 24-watt electric lamp *L* were diffused by opal screens, and passed through two optical systems to the photo-electric cell *A*. A special shutter *F* enabled the beams (of equal intensity) alternately to illuminate the cell. The photo-electric current produced by the illumination was amplified and balanced as in the usual null method. The stain, the density of which was to be measured, was placed in the path of one beam (at *B*), and a standard neutral optical wedge *W*, connected mechanically to a vernier and scale *V*, graduated in density units, in the path of the other beam of light. The optical wedge was adjusted until the galvanometer *G* gave a null deflection for either

<sup>1</sup> F. C. Toy, *J. Sci. Inst.*, 1927, 4, 369-75.

<sup>2</sup> *Ibid.*, 1924, 1, 362-5.

position of the shutter. The intensities of the two beams alternately incident on the cell were then equal. The reading on the wedge scale was a measure of the optical density of the stain, the units being dependent on the gradation and density characteristics of the optical wedge chosen. The true optical density  $D$  (i.e. the logarithm of the inverse of the transmission to base 10) for the wedge used in these experiments may be expressed in terms of the scale readings as follows:—

$$D = 0.375 (\text{Density Reading} - 0.15) + 0.92.$$

The true optical density of a stain (obtained by subtracting the optical density of the filter paper from that of the paper with stain) was 0.375 times the difference between the respective scale readings.

The stains, obtained on a Whatman filter paper (R.F. special), by means of a hand pump (capacity 180 c.c. per stroke), were circular, and approximately 0.60 cm. in diameter. It is essential that the filter paper should

be of as uniform density as possible, as variations in the transmission of the paper limit the accuracy of the method.

Samples of the particulate cloud to be estimated were drawn through the filter strips by one or more strokes of the pump until a series of stains of varying densities was obtained for measurement with the density meter. The errors due to paper variations were minimised by examining a series of stains in this manner.

Conditions for the use of the photo-electric density meter should be constant. The lamp current

FIG. 1.—Diagrammatic sketch of apparatus.

was maintained at 3.5 amperes, and the valve filament current at 0.25 amperes (Osram D.E. 5B valve, plate voltage 84 volts). After a reasonable time had elapsed for the battery potentials to reach a steady state, the mean optical density of the paper for each strip was measured, and this value used to obtain the optical densities of the respective stains on each filter strip.

A preliminary calibration is necessary for each type of cloud examined. For any given smoke cloud, a series of stains was obtained, and the corresponding concentration of the disperse phase estimated gravimetrically. The concentrations were determined by drawing known volumes of the cloud through small dry asbestos filters, carefully drying the filters, and obtaining the mass increase by means of a balance, sensitive to  $\pm 0.002$  mgm. A calibration curve is thus obtained which gives the relationship between the optical density of the stain and the mass of the disperse phase in the stain and hence the cloud concentration.

The concentration of any cloud of the same substance and characteristics may be estimated from this calibration curve by obtaining a series of stains and determining the stain optical densities. Alternatively, if a known concentration  $C$  produces a stain density  $D$  for  $n$  pump strokes, and an unknown concentration produces a stain with the same optical density  $D$  for  $m$  pump strokes, it follows that the unknown concentration is  $\frac{n}{m}C$ , since the mass of the disperse phase in the stain must be identical in the two cases.

## Results.

### 1. Coal Fire Smokes.

A small brazier served as the source of the clouds and was introduced into a chamber (approximate volume, 10 cubic metres), for short intervals of time, depending upon the required concentrations of smoke. Fires emitting various amounts of smoke were employed, and dilutions of any cloud were obtained by the admixture of filtered air. The resulting clouds were fanned continuously while mass estimations and stains were obtained simultaneously.

An examination of the particles constituting the cloud obtained from a moderately smoky fire, as used for stain series No. 4 (Table II.), collected by a sedimentation method, afforded the results shown in Table I., for particles visible under the ordinary microscope. Sub-microscopic particles also were possibly present in these clouds.

### Discussion of Results (Coal Fire Smokes).

The relationship between the optical density of stains obtained from coal fire smokes and the mass of the disperse phase in the stains is shown graphically in Fig. 2.

It is somewhat surprising that the clouds from three coal fires burning under different conditions should afford consistent results. Analysis indicated that a very high percentage of carbon was present in these coal fire smokes. Drying the stains had little or no effect on the optical density measurements. The percentage error of the estimation of concentration for individual stains is of the order of  $\pm 10$  per cent. This is mainly due to the variations in the optical transmission of the filter paper. Some difficulty was experienced in obtaining a suitable filter paper of uniform transmission, but the percentage error is reduced to less than  $\pm 5$  per cent. if a series of stains is obtained and used for the estimation of concentration.

It was found that, with the conditions of these coal fire smoke experiments, the optical transmission of the stain is inversely proportional to the square of the mass of the disperse phase in the stain. It is possible that this relationship exists only for the particular optical arrangement used in the photo-electric density meter. The validity of this method, which is essentially comparative, does not depend upon the accuracy of the optical density measurement.

It is inadvisable to use very dense stains. In practice, it was found necessary to limit the mass of disperse phase in the stain to less than  $4.0 \times 10^{-3}$  grammes. Inconsistent results have been obtained when this amount has been exceeded. These are probably due to factors governing the transmission of light through such stains. The filter may be affected by strain due to the increased resistance to air flow.

### 2. Owens' Automatic Recording Air Filter.

This photo-electric method of estimating the density of stains on filter paper was considered of interest in connection with automatic filter records.<sup>a</sup> Dr. J. S. Owens kindly submitted filter discs with various records for examination.

An atmospheric pollution record (Feb. 12/13, 1934) consisted of forty-five stains of various densities, some of which had been assessed shade numbers by Dr. Owens. The maximum variation in the optical density of the filter paper (without stains) was approximately 0.041. These readings were obtained by avoiding watermarks, print and flaws in the paper, the presence of which near or within the stain area would render

accurate assessment of the optical densities of the stains practically impossible. In the recorder, the filter paper in the region of each stain is subjected to compression. The mean optical density for the compressed areas was 0.026 greater than that for the normal filter paper. This was taken into consideration in estimating the stain densities.

FIG. 3.—Relationship between optical density and shade number for certain atmospheric pollution stains.

The curve showing the relationship between optical density and Owens' shade number, obtained from the results given in Table III., is shown in Fig. 3. It may be observed that the accuracy of the method is of the order of  $\pm 1.5$  Owens' shade numbers, the limits of visual assessment presumably being  $\pm 0.5$  shade number. The discrepancies shown

in the correlation may be attributed almost wholly to the variation in the optical density of the filter paper used. If a more suitable filter paper were obtainable, having a reasonably constant optical density, a better correlation would result. Alternatively, if it were possible to obtain a larger area of stain, a number of density readings for each stain could be obtained and a mean value would reduce the possible errors of individual readings.

The optical density of the atmospheric pollution stains was more nearly proportional to the mass of the disperse phase in the stain than was the case with coal fire smoke stains. This may be attributed to the different nature of the disperse phase. It is possible that the texture of the filter paper used influences the distribution of the disperse phase in the stain.

The mass of the disperse phase in the Owens' filter stain was compared with that of stains of similar density obtained from coal fire smokes. Owing to the different forms of the two calibration curves, it is not possible to give a constant value for the mass in a stain of unit shade number on the Owens' scale. Thus, a stain of shade number 20 gave an approximate value of 0.29 mgm./cu. metre for unit shade number, while for a stain of shade number 2, a value of 0.26 mgm./cu.m. was obtained for unit shade number. The value given by Dr. Owens for unit shade number is 0.32 mgm./cu. metre.

Although it is not strictly accurate to compare the atmospheric pollution stains with those obtained from coal fire smokes, it may be concluded that the disperse phases in both have much in common, the concentrations required to give a stain of given density being not very different in the two cases.

### **Application of Calibration Curve to the Estimation of Stain Shade Numbers.**

Two filter disc records of atmospheric pollution were supplied by Dr. Owens, the stains of which were not assessed in shade numbers. Density readings were obtained and corresponding shade numbers estimated from the calibration curve. The discs were then returned to Dr. Owens, who kindly assessed his standard shade numbers.

Generally speaking, the results indicated a fair agreement between the visual and photo-electric methods of estimating the stain densities. There appeared to be several anomalous results and, of these, some were definitely attributable to flaws in the paper in or near the stain area. A possible explanation of the remaining cases is that the appearance of the stain by reflected light may not always be a true indication of the mass of the disperse phase in the stain. It is conceivable that an occasional structural variation of the filter may influence the penetration of the disperse phase into the filter. If more of the mass enters the body of the paper, the surface density is decreased and the resulting stain would appear less dense by reflected light than if all the disperse phase remained on or near the filter surface. The photo-electric method, using light transmitted through the stain, would give a measure of the whole mass in the two cases.

### **Conclusions.**

The photo-electric method has proved satisfactory for simple estimations of such coal fire smokes as described. The accuracy of the method is dependent on the uniformity of optical transmission of the filter paper, but with a reasonably good filter paper, and by using a series of stains, the percentage error of estimation of cloud concentration should not exceed  $\pm 5$  per cent.

For estimating atmospheric pollution, with the filter discs at present employed, the photo-electric method possesses no advantage over the

visual method. The variations in the texture of the filter papers, and the presence of print, render the photo-electric method liable to error. With a more uniform filter paper, and a larger stain area, the photo-electric method might be used to advantage.

### Summary.

A photo-electric density meter has been employed to determine the optical density of stains obtained by drawing known volumes of aerosols through restricted areas of filter paper. The relationship between the optical density of the stains and the mass of disperse phase in them has been determined gravimetrically, and a calibration curve obtained for coal fire smokes. The accuracy of the method is limited by the variations in the optical transmission of the filter paper, but an accuracy of estimation of cloud concentration of  $\pm 5$  per cent. has been obtained by utilising a series of stains for each concentration. The method has been applied to the measurement of the optical density of stains of atmospheric pollution obtained with the Owens' Automatic Recording Air Filter. The Owens' shade numbers and the optical densities of the stains have been correlated and the limits of accuracy of the method have been found to be of the order of  $\pm 1.5$  standard shade numbers. A comparison with stains from coal fire smokes has indicated a similarity in the nature of the stains. Advantages and disadvantages of the two methods have been discussed.

## ON THE RATE OF CHARGING OF DROPLETS BY AN IONIC CURRENT.

BY N. FUCHS, I. PETRJANOFF AND B. ROTZEIG.

*Received 24th February, 1936.*

The process of charging floating particles by an ionic current, which plays a very important rôle in the electrical precipitation of smoke and dust, has been the object of a large amount of experimental and theoretical work. This work, however, has been devoted almost exclusively to the study of the final (maximum) charge acquired by the particles in an ionic atmosphere as a function of their size, the applied field-strength, ion concentration, etc. The kinetics of the charging process, on the other hand, have been studied only \* by M. Pauthenier <sup>1, 2</sup> and by J. P. Gott.<sup>3</sup>

When the particle is so large that the effects due to diffusion of the ions towards the particle, and to mirror forces, can be neglected, the kinetics of the charging of a spherical dielectric particle can be expressed by the following equation <sup>1</sup> (assuming that each ion striking the surface of the particle gives up its charge):

$$Q = \left(1 + 2 \frac{k-1}{k+2}\right) E a^2 \left( \frac{\pi n u e l}{1 + \pi n u e l} \right), \quad . \quad . \quad (1)$$

\* In the work of Arndt and Kallmann <sup>4</sup> we find an investigation of the last stage only of the charging process, when the final charge is practically attained and the rate of charging becomes exceedingly small.

<sup>1</sup> M. M. Pauthenier et M. Moreau-Hanot, *J. de Physique*, 1932, 3, 590.

<sup>2</sup> Pauthenier et Agostini, *C.R.*, 1934, 199, 705.

<sup>3</sup> J. P. Gott, *Proc. Roy. Soc.*, 1933, 142A, 248.

where  $Q$  is the charge acquired by the particle in the time  $t$ ,  $a$  the radius,  $k$  the dielectric constant of the particle,  $E$  the strength of the external electric field,  $n$  the number of ions per c.c.,  $u$  their mobility, and  $\epsilon$  the electronic charge. For a conducting sphere, the expression  $1 + 2\frac{k-1}{k+2}$  becomes equal to 3.

Pauthenier and Agostini<sup>2</sup> proved the validity of equation (1) experimentally, using 3 to 4 mm. diameter steel balls, falling freely through a cylindrical electric precipitator, parallel to its axis. The field-strength was measured by these authors by means of an incandescent probe, while  $n$  was calculated from the equation

$$n = E/4\pi r\epsilon \quad (2)$$

( $r$  distance from the axis of the cylinder). This equation is well known to be valid for the space where the field-strength is constant. The velocity of fall was determined by photographing the balls under intermittent illumination, and the charge acquired by the balls was measured by means of an electrometer. A very close agreement between the theoretical and experimental values of the charge was found.

In the work of J. P. Gott<sup>3</sup> the ionic atmosphere was produced by means of X-rays, water drops of 4.4 mm. diameter being used, and only the initial rate of charging was determined. The measurements were considerably less exact than in the work of Pauthenier, but nevertheless quite satisfactory results were obtained.

For particles of the order of  $1\mu$  radius and smaller (which it is especially difficult to precipitate in practice), the influence of diffusion of the ions and of mirror-forces may, however, be so considerable that equation (1) must be regarded in this case as giving only the lower limit of the rate of charging. The smaller the particles the larger will be the difference between the actual values of the charge and those calculated from (1).

The theoretical calculation of the rate of charging, taking into account the two above-mentioned factors, seems to be exceedingly difficult. The difficulty is especially increased by the fact that the particles under consideration are of the same order of magnitude as the mean free path of the ions. An experimental study of the kinetics of charging in this region of particle size is therefore indispensable.

The ingenious method employed by Arndt and Kallmann<sup>4</sup>—the direct charging of a droplet by ions within a Millikan chamber, periodically interrupting the ionisation in order to measure the charge acquired meanwhile—allows the use of but relatively small field-strengths and current-densities, i.e., of conditions widely differing from those used in industrial electric precipitation. We chose therefore another method, similar to that of Pauthenier. In this method, a narrow air-jet containing floating particles is passed along the axis of a precipitator and thereupon sucked into an ultramicroscopic cell, where the size and charge of the particles are determined. We further used a cloud of uncharged droplets obtained by condensation of oil-vapours, thus avoiding the charges produced on droplets by spraying. It is clear that the rate of charging of a particle in air of the same velocity as itself will be not different from the rate in still air.

### Experimental Details.

The general arrangement of the apparatus is shown in Fig. 1. The cylindrical precipitator BCB consists of three sections separated by thin insulating sheets. The outer sections, BB are earthed directly, while the inner section, C made of fine wire-gauze, is earthed through a sensitive galvanometer G. TT are insulating top-plates. The diameter of the precipitator is 31 cm., the total height is 37 cm., and the height of the inner section C is 7.2 cm.

The negative discharging electrode D, made of a silver-wire 0.5 mm. in diameter, is fixed accurately along the axis of the cylinder BCB. The voltage is generated by a transformer connected with a kenotrone and a condenser of 3000 cm. capacity. As we used relatively small currents, of

FIG. 1

about  $10^{-4}$  A, at voltages of about 30 KV, the smoothing effect of the condenser was very high; the periodic oscillations of the current, measured by means of an oscillograph, did not exceed 3.5 per cent.

The cloud-jet is let into and out of the precipitator through thin-walled, silver-coated and earthed glass tubes \* JJ', placed strictly along the same axis. The distance from this axis to the inner walls of the precipitator is 0.5 cm. From the tube J' the charged cloud enters the ultramicroscopic cell K and can be stopped there without interrupting the circulation of the cloud, which is sucked into J' by means of the pump E. This pump at the same time blows the air through a cotton-wool plug L in the cloud-producer N, which consists of a hollow copper cylinder heated electrically and containing the oil (mineral oil with density 0.91). The hot air-stream

\* We could not find sufficiently smooth and thin-walled metallic tubes of the required size.

saturated with oil-vapours mixes with the cold air flowing through the tube O. The cloud produced by condensation is thereupon diluted by the air flowing through P, in order to diminish the concentration of droplets. A large amount of oil condensing on the walls of the tubes is tapped off through Q. This oil was then used for the determination of the dielectric constant\* (2.56) and the density (0.895) of the droplets. Varying the rate of flow in the tubes O and S and the temperature of the oil, we could obtain clouds of different particle size, with droplets ranging from  $0.5\mu$  to  $3\mu$  radius. The droplets settling on the walls of the tube J form an oil layer, which continually flows down and appreciably diminishes the width of the orifice. In order to prevent this, the lower part of the tube was constructed as shown in Fig. 1. The rate of flow in all parts of the apparatus was regulated with stop-cocks and measured by flowmeters FF. HH are air-buffers, and M—pressure regulator.

A number of difficulties had to be contended with, in obtaining a steady narrow cloud jet having practically a constant linear velocity for a length considerably in excess of the diameter of the tubes JJ'. Only in this case could the time of passage of the droplets through the ionic atmosphere be determined with sufficient accuracy whilst, at the same time, the distortion of the electric field caused by the tubes could be neglected.

It was found that, for each width of the jet, there exists a corresponding optimal velocity of flow, at which the jet has the maximum of stability. At velocities considerably differing from the optimal, the jet breaks down at a very short distance from the orifice. We found, further, that very narrow jets widen, *i.e.*, their linear velocity decreases markedly with the distance from the orifice. On the other hand, the scattering of the jet by the ionic current made it impossible to increase appreciably the length of the jet, *i.e.*, the gap between the tubes JJ', and therefore, as already said, to use wider jets.

We finally chose a jet of 3.5 mm. diameter and a mean linear velocity of about 3 metres per second. Under these conditions, the cloud jet, observed in the light of an arc-lamp, has sharp boundaries, and its width measured by means of a horizontal microscope remains constant to within 2 to 3 per cent. throughout its length (5.2 cm.). This shows that the linear velocity remains constant to within 4 to 6 per cent. The whole of the jet is sucked without loss into the tube J' of a larger diameter (8 mm.) To prevent loss, the rate of suction must be appreciably larger than the rate of flow of the cloud in J.

It must be noted that there is a definite distribution of velocities within the jet, apparently similar to that of a Poiseuille's flow, but differing from it by the fact that at the boundary the velocity is not equal to zero. An experimental study of this distribution in such a narrow jet seems to be very difficult, and was not undertaken by us. Its general character can be seen from the scattering of the measured values of charges about the mean values (*cf.* below). We limited ourselves to the determination of the average velocity from the rate of flow in the tube J and the cross-section of the jet. From this and from the distance between the tubes JJ', we calculated the average time of passage of droplets through the ionic atmosphere with an accuracy of about 5 per cent., the chief error resulting from inaccuracy in measuring the width of the cloud-jet. The error resulting from the fact that a certain number of ions are sucked into the tube J', where they may also be caught by the droplets, must be exceedingly small, as a rough calculation shows.

The jet is naturally made still less steady by the corona discharge, and is deflected from its straight path and dispersed sooner for stronger and stronger current densities. As it was impossible for the aforesaid reasons to shorten the jet appreciably, we were forced to use relatively

\* We are much indebted to Mr. V. Vassiljeff who made this determination for us.

small current-densities up to about  $10^{-8}$  A/sq. cm. The corresponding values of the field-strength and ion-concentration are 1000 V/cm. and  $3.5 \times 10^7$ /c.c. The deflection and spreading of the jet, resulting from the charges acquired by the droplets, limits the applicability of the method here described to a study of the initial stage of the charging of droplets in an electric precipitator, namely up to about  $\frac{1}{4}$  to  $\frac{1}{2}$  of the maximum charge.

The use of small current-densities forced us to employ a precipitator considerably larger than the one used at the first stage of this work (12 cm. diameter). With this we were obliged to have a potential on the discharging electrode differing so little from the starting potential, that the slightest fluctuations in the line voltage caused a marked change of the ionic current. In the 31 cm. precipitator the constancy of the current was quite satisfactory.

The density of the ionic current passing through the cloud jet was calculated from the total current flowing through the inner section of the precipitator. In order to ascertain that the current density was constant throughout the circumference of the section, and not changed appreciably by distortion of the field due to the tubes JJ', a rectangular hole 5.2 cm. high and 1 cm. wide was made in the wall of the section C just opposite the cloud jet. A plate made of fine wire-gauze was inserted in the hole providing narrow air-gaps between the plate and the wall. The plate was connected with the galvanometer G. By measuring successively the current flowing through the whole section and through the plate, we found that the ratio of these currents differed from that of the corresponding areas by not more than 3 to 4 per cent. Thus the reliability of the current density values, calculated as mentioned above, was proved. The accuracy of the current-density measurements can also be considered to have the same value of 3 to 4 per cent.

FIG. 2.

Both the size and the charge of droplets were measured in the cell K by the photographic oscillation method worked out in this laboratory\* as a development of an ingenious idea of Wells and Gerke.\* The droplets are allowed to fall under the force of gravity and at the same time they are compelled by an alternating electric field to oscillate in a horizontal direction. Photographing the zig-zag paths of the droplets, we can first determine the size of the droplets from their rate of fall, and then their charge from the horizontal velocity\* (cf. Plate I., representing one of the photographs made in this work).

The construction of the cell is shown in Fig. 2. It is made from a massive copper block in order to avoid convection currents. A is the illuminating objective, BB the electrodes producing the horizontal field. The cloud is let in and out through the tubes CC. The adjustable spherical mirror D serves to reflect the illuminating beam back in order to avoid the photophoresis of the droplets. The mean error in the determination of charge by this method is about 2 to 3 per cent. for droplets of radius

\* Fuchs und Petrijanoff, *Kolloid-Z.*, 1933, 65, 171.

\* Wells and Gerke, *J. Amer. Chem. Soc.*, 1919, 41, 312.

\* It may be mentioned that in the work of Wells and Gerke one of the motion-components was due not to gravity but to convection or photophoresis. Therefore these authors could determine the charges of droplets only if they knew their size beforehand, or vice versa.

FIG. 3.— $t=0.0165$  sec.;  $j=3.18 \times 10^{-9}$  A/sq. cm.;  $E=556$  V/cm.;  $n=1.98 \times 10^7$ /c.c.

FIG. 4.— $t=0.0172$  sec.;  $j=5.51 \times 10^{-9}$  A/sq. cm.;  $E=732$  V/cm.;  $n=2.70 \times 10^7$ /c.c.

$> 1\mu$  and about 10 per cent. for droplets of  $0.6\mu$  radius (due to the Brownian motion). The error in determination of the size is about three times less.

A source of error in these experiments might be expected in the settling out on the walls of the tube  $J'$  of more highly charged particles, due to mirror forces and to the mutual electrostatic repulsion between droplets. A rough calculation showed, however, that this circumstance could not have any practical significance under the conditions of our experiments.

The same can be said about the effect due to a screening off of the ionic current by other droplets. As their concentration in the cloud jet was about  $10^4$  per c.c., the area screened by the droplets of say  $2\mu$  radius in a cloud layer 3.5 mm. thick is only

$$\pi \times (2 \times 10^{-4})^2 \times 10^4 \times 0.35 = 4.8 \times 10^{-4}$$

of the total area.

FIG 5.— $t = 0.015$  sec.;  $j = 9.1 \times 10^{-9}$  A/sq. cm.;  $E = 940$  V/cm.;  $n = 3.4 \times 10^7$ /c.c.

### Experimental Results.

Some of the results obtained in this work are shown in Figs. 3 to 5. The curves are plotted according to the equation

$$Q = \left(1 + \frac{k-1}{k+2}\right) \pi a^2 j \left(\frac{1}{1 + \pi j/E}\right) \quad (3)$$

derived from (1) by substituting  $j/E$  for  $une$ . ( $j$  = current density). The values of  $t$  and  $j$  are shown below the figures;  $k$  is as large as 2.56. Taking for the mobility of the ions the value  $1.75$  cm./sec./V/cm. which gave the best agreement between the theoretical and experimental values of the field-strength in the work of Pauthenier and Moreau-Hanot,<sup>1</sup> we obtain from Townsend's equation,

$$E = \sqrt{\frac{4\pi j r}{u}}$$

corresponding values of field-strength  $E$  and ionic concentration  $n$ . The error arising from the fact that  $E$  was not measured directly, but calculated, could not affect the results appreciably. If, for instance, we take for the mobility the value 1.9 instead of 1.75, the right side of the equation (3) will be reduced only by 1 to 1.5 per cent. The charges acquired by the droplets in these experiments are about 0.2 to 0.3 of the maximum charges.

The experimental points on each curve are taken from several (4-5) photographs. It was very difficult to maintain exactly the same values of ionic current and velocity of the jet in all experiments; they varied as much as about 3 to 4 per cent. In order to be able to put all experimental points on the same diagram, the values of the charges were recalculated according to equation (3).

The scattering of the measured charges about the mean values is due, as already stated to distribution of velocities in the jet, and for smaller particles, besides that to statistical fluctuations.

As can be seen from the diagrams, the mean values of the measured charges lie satisfactorily on theoretical curves. It seems, however, that the data so far obtained are not sufficient to determine definitely how exactly equation (3) holds for the smaller droplets of radius  $< 1\mu$ . The question will be studied more carefully in this laboratory in the near future.

It must be noted that the method described in this paper is not limited to relatively large particles, whose charge and size can be measured by the "oscillation" or Millikan methods. By measuring the total charge of a cloud by an electrometer and determining the number of particles contained in it, we can measure the charging-rate of particles of any aerosol. This can be accomplished also by measuring the mobility of the charged particles in an electric field provided their size is known.

The method described can be further used to obtain unipolarly charged aerosol with a considerable degree of uniformity of the charges, which is hardly attainable by other methods.<sup>7</sup>

### Summary.

1. A method for the determination of the rate of charging of floating particles by an ionic current is described. It consists of passing a narrow cloud-jet parallel to the axis of a cylindrical electric precipitator, and measuring the charges acquired by the particles in it.

2. The experiments were made with oil-droplets ranging from  $0.5\mu$  to  $3\mu$  radius. The size and charge of the droplets were measured by the "oscillation" method. Current densities of about  $3$  to  $10 \times 10^{-4}$  A/sq. cm. and times of charging of about 0.01 to 0.02 sec., were used.

3. A good agreement between the mean values of the measured charges and theoretical values calculated neglecting the effects due to diffusion of ions and to mirror-forces, was obtained for the whole range of sizes studied.

We are indebted to the State Gas-Purifying Trust for financing of this work.

# AN EXACT THEORY OF THE COAGULATION OF SPHERICAL PARTICLES ARISING FROM THERMAL AGITATION.

BY W. R. HARPER.

*Received 6th March, 1936.*

A general theory of coagulation must first deal with its most fundamental aspect—the bringing together of the coagulating particles by thermal agitation. Comparison with experiment is then possible, since this simple mechanism is almost certainly adequate to account for the coagulation of smokes, and appears also to be adequate to account for the coagulation of some colloidal solutions. A theoretical treatment for spherical particles has been given by Smoluchowski,<sup>1</sup> and his results confirmed experimentally by Tuorila, and by Patterson and Cawood. The present author however, has given reasons for doubting the validity of the interpretation of these experiments, and has shown that the theoretical treatment as presented by Smoluchowski is open to serious criticism, being self-contradictory. The coagulation coefficient was obtained by him by a consideration of the diffusion of particles in a concentration gradient which was itself established by the coagulation process, and which was therefore *not* present previous to the coagulation, i.e. not present during the motion which actually determined the rate of coagulation. His treatment might therefore very well give an incorrect value for the coagulation coefficient. Moreover, an alternative treatment of the author's <sup>2</sup> (subsequently corrected <sup>3</sup> for a numerical error) gave a value for the coagulation coefficient which was three-quarters that obtained by Smoluchowski. The mathematical methods employed, however, being approximate, could only suggest, and not prove, that Smoluchowski's result was numerically incorrect.

The possible existence of a considerable discrepancy between theory and experiment at the very basis of coagulation theory was a serious matter demanding further investigation, and it was therefore important to determine the true theoretical value of the coagulation coefficient by a method at the same time both logically rigorous and mathematically exact. It is possible to improve the author's previous treatment so as to conform to these standards, and this will be done in the present paper. The result obtained is identical with that of Smoluchowski.

It might therefore be thought to have been more satisfactory to have attempted a reconsideration of Smoluchowski's own treatment, in the hope of obtaining it in a revised form freed from the objections already mentioned. The author has made such an attempt. Further doubtful steps in the argument were thereby revealed, some being concerned with factors of two. At the same time, it did appear that by presenting the argument in a different form, the coagulation coefficient *could* be made to depend on a calculation similar to that of Smoluchowski's, and probably leading to the same value for the coagulation coefficient. Hitherto,

<sup>1</sup> *Z. physik. Chem.*, 1917, **92**, 129.

<sup>2</sup> *Trans. Faraday Soc.*, 1934, **30**, 636.

<sup>3</sup> *Ibid.*, 1935, **31**, 774.

however, the author has not succeeded in obtaining this argument in a form exempt from criticism, so it will not be given here.

### The Collision Problem.

If collision always leads to coagulation, the coagulation coefficient may be written down once the frequency with which particles collide is known. It is irrelevant for the purpose of the present calculation whether the collisions leading to coagulation are collisions with contact, or merely approach to within a certain critical distance. We therefore consider a system of points (the centres of the spherical particles) which move along tracks determined by random collisions with the molecules of the surrounding medium, and therefore by the laws of the Brownian movement, and which are said to be in  $\sigma$  collision when they are within a distance  $\sigma$  apart. They are contained in a volume which is very large compared with the probable path of a particle before it suffers a  $\sigma$  collision, so that the collision frequency is the same as for a distribution of infinite extent. If the particles differ in size, we consider the frequency of collisions of particles of a certain size, characterised by centres with a diffusion coefficient  $D_1$ , with particles of another size, characterised by centres with a diffusion coefficient  $D_2$ , their concentrations being  $n_1$  and  $n_2$  respectively. This collision frequency will be unaffected by the presence of the other particles if, as will be assumed, the particulate volume is large compared with the volume of a particle (or its sphere of action).

We are dealing with relatively high concentrations, so a large number of collisions can occur before the concentration is appreciably affected, and the collision frequency must be calculated from what happens during such a time. The initial distribution of each set of particles in space is the distribution at any stage of the coagulation, and has been reached by the processes of diffusion and coagulation. The former leads to a random distribution, and the latter does not disturb it. But the distribution of one set of particles about any particle of the other set, averaged over all such particles, is not random, being disturbed by coagulation. This is because some particles of a random distribution are actually in collision, have therefore coagulated, and really belong to a set of particles characterised by another diffusion coefficient. They must therefore not be included in the averaging. This eliminates all particles of the second set which have particles of the first set closer to them than a distance  $\sigma$  between centres. The required distribution of the centres of the first set about those of the second has therefore zero concentration up to a radius  $\sigma$ . The distribution of the particles of the first set about any eliminated particle of the second set is, however, random outside the radius  $\sigma$ , from which it follows that the required distribution of the centres of the first set about those of the second has a uniform concentration  $n_1$  of randomly distributed centres outside the radius  $\sigma$ .

We may take this initial distribution of centres and use appropriate equations of motion to investigate how long it will be on the average before another collision occurs in the system, from which the collision frequency may be deduced. It is this method which leads to mathematics similar to Smoluchowski's, but we shall not pursue it further, since it is not the most direct line of attack. The result obtained by following it through comes entirely from the initial slight deviation from a random distribution, and therefore depends on a logical subtlety,

since it is clear from physical intuition that the deviation is irrelevant in a direct calculation of the collision frequency, which depends on how quickly the centres move about, and on their average distance apart, and not on their *precise* distribution. That the precise initial distribution is not important will now be proved.

In a direct treatment we have to consider each centre of the second set moving among the first set, calculate its probable lifetime before collision, and average over all the second set. This gives the probable lifetime of a centre of the second set, and hence the collision frequency. Now the departure of the initial distribution from a random one affects the average lifetime before collision in that some second set centres of a random distribution are excluded from the averaging, and to these centres belongs a probable lifetime which is shorter than the average for the random distribution. The true average is therefore longer than the average for a random distribution by an amount which is equal to the difference between the average for the actual distribution and the average for the excluded centres multiplied by the fraction of the centres excluded. The former is of the order of magnitude of the true average, and the latter is equal to the fraction of the centres of the second set which are in collision at any time, which is equal to the volume of a sphere of action of the second set divided by the particulate volume for the first set, and this ratio has been postulated to be very small. We shall, therefore, incur a negligible error by calculating the average lifetime on the assumption that the initial distribution is strictly random. This is actually the case for our two sets of centres if the sphere of radius  $\sigma$  is a pure mathematical fiction, so that, on collision, interpenetration instead of coagulation occurs. Again referring to physical intuition, it is clear that the assumption of interpenetration will not affect the collision frequency, since its magnitude depends on how quickly the centres find each other, and not on what happens during a collision. We shall calculate the collision frequency for a system in which interpenetration occurs.

In spite of what has just been said, it is clear that the rate at which centres find each other is correlated with the time they remain within a distance  $\sigma$  during an *interpenetrating* collision, and we shall now make use of this correlation. Consider any given large volume  $V$ , containing  $n_1 V$  centres of the first set, each centre being surrounded by a sphere of radius  $\sigma$ . Since the particulate volume is large compared with the volume of such a sphere, the spheres overlap to a negligible extent, and the fraction of the volume  $V$  occupied by them is  $\frac{4}{3}\pi\sigma^3 n_1 V / V = \frac{4}{3}\pi n_1 \sigma^3$ . Now the distribution of the centres of the second set is purely random, so if we consider a particular centre of the second set, the chance that it is located in a particular volume inside  $V$  at any time is just the ratio of this volume to the total volume  $V$ , irrespective of the position or shape of the volume considered. The probability that the centre of the second set is in  $\sigma$  collision with some centre of the first set at any time is therefore  $\frac{4}{3}\pi n_1 \sigma^3$ . Another expression for this probability may be obtained from a consideration of the life history of the centre of the second set during a long time  $T$ . During this time, it suffers  $\nu_2' T$  collisions, where  $\nu_2'$  is the collision frequency for a single centre of the second set. If the average duration of a collision is  $\tau'$  it is in collision for a total time  $\nu_2' T \tau'$ . The fraction of the time it is in collision is  $\nu_2' \tau'$ , and this is equal to the probability of finding it in collision at any time. We therefore have  $\frac{4}{3}\pi n_1 \sigma^3 = \nu_2' \tau'$ . The collision frequency  $\nu'$  for the system is  $n_2 \nu_2'$ , and is therefore  $\frac{4}{3}\pi n_1 n_2 \sigma^3 / \tau'$ .

We have now to resolve an ambiguity in the definition of the average duration of a collision. If we consider a centre which comes from infinity to collide with another centre, and then returns to infinity, it is clear that owing to the tortuous nature of its track it will, in general, approach to within a distance  $\sigma$ , and recede to a greater distance several times, thus making a multiple collision. Moreover, the multiplicity will be very high if the mean free path of the centre (between bends in its track) is small compared with  $\sigma$ , as is the case in the present problem. But the probability of return to within the distance  $\sigma$  is only appreciable if the

FIG. 1.—AB and CD are tracks which are not members of the subset. EG and HK are two tracks which are members of the subset, HK being a track showing multiplicity in collision. The contribution of these two tracks to the time average comes from the sections within the sphere of radius  $\sigma$ , i.e. from the sections of track which are thickened. The sections of track FG and JK are typical of tracks starting at F and J respectively.

centres have not separated to a distance many times  $\sigma$ , that is, if they have not been likely to have collided with some other centre. When, therefore, the first collision of a multiple collision is sufficient to lead to coagulation, the rest are wasted from that point of view, and the multiple collision counts as a single collision.<sup>4</sup> What we require, therefore, is the collision frequency in the sense of the number of different centres visited per second, and in calculating the value of  $\tau'$  we must sum up all the individual times spent within

the distance  $\sigma$  that refer to the different collisions of a multiple collision.

### The Case of $D_2 = 0$ .

We shall consider first the case of  $D_2 = 0$ , so that only particles of the first set move. The procedure for calculating the average duration of a collision then reduces to the following, the details of which will perhaps be understood more clearly on reference to Fig. 1, which is purely schematic. We take a sphere of radius  $\sigma$  whose centre corresponds with the centre of a particle of the second set and is therefore fixed, and a set of tracks characterised by a diffusion coefficient  $D_1$  which start at

<sup>4</sup> The situation is very different if collision does not invariably lead to coagulation. See Fuchs, *Z. physik. Chem.*, 1934, 171A, 199.

random at infinity and return to infinity, and we consider the subset of those tracks which pass through the sphere. We add up the total length of track within the sphere, express it as a time, and divide by the number of tracks in the subset, thus obtaining  $\tau'$ .

Now the subset is chosen from the set in the following manner. Starting at infinity at the beginning of a track, its course is followed. If it returns to infinity without passing through the sphere it is excluded from the subset. If it reaches any point on the surface of the sphere, it is immediately included in the subset. The sections of track in the subset which lead up to the sphere are therefore not typical of Brownian movement tracks starting at the surface of the sphere, since some of the tracks defined in this way would pass through the sphere, and the actual sections of track do not. But assigning a track in the set to the subset in the manner stated does not affect the completely random nature of the track once it is so assigned, so the sections of track in the subset executed after reaching the sphere are typical of Brownian movement tracks starting at the surface of the sphere, and moreover, they include all the track within the sphere.  $\tau'$  may therefore be calculated as the average time spent within the sphere by centres starting at a point on its surface and moving along Brownian movement tracks to infinity. When adding up the total time spent by the centres within the sphere and dividing by their number, it is irrelevant which centre contributes which element of time, so we may obtain the average from the distribution of the centres given as a function of the time, without having to follow the detailed history of the individual centres. The distribution function required is that for a set of centres starting together from a point at time  $t = 0$ , and then diffusing outwards, and is well known.

If  $Q$  centres start from the point on the surface of the sphere, and at time  $t$  there are  $q(t)$  within it, then

$$\tau' = \frac{1}{Q} \int_0^\infty q(t) dt.$$

Now, the number of centres that are situated within a spherical shell defined by  $r$  and  $r + dr$  whose centre is the starting-point is

$$\frac{Q}{2\sqrt{\pi}} (D_1 t)^{-\frac{3}{2}} r^2 e^{-\frac{r^2}{4D_1 t}} dr.$$

The fraction of these inside the sphere of radius  $\sigma$  is equal to  $1/4\pi$  times the solid angle subtended by the spherical cap of intersection of the two spheres at the starting-point, and is  $\frac{1}{2} \left(1 - \frac{r}{2\sigma}\right)$ . The total number inside the sphere is therefore

$$q(t) = \int_0^{2\sigma} \frac{Q}{4\sqrt{\pi}} (D_1 t)^{-\frac{3}{2}} r^2 \left(1 - \frac{r}{2\sigma}\right) e^{-\frac{r^2}{4D_1 t}} dr,$$

$$\text{and} \quad \tau' = \frac{1}{4\sqrt{\pi}} \int_0^\infty \int_0^{2\sigma} (D_1 t)^{-\frac{3}{2}} r^2 \left(1 - \frac{r}{2\sigma}\right) e^{-\frac{r^2}{4D_1 t}} dt dr = \frac{\sigma^2}{3D_1},$$

whence the collision frequency  $\nu' = 4\pi n_1 n_2 \sigma D_1$  for  $D_2 = 0$ , the value obtained by Smoluchowski.

### The General Case.

The earlier approximate treatment of the author gave reason to suppose that the collision frequency for both sets of particles moving

could not be obtained from the case of  $D_2 = 0$  merely by substituting  $D_1 + D_2$  for  $D_1$  in the formula. It will now, however, be shown that an exact treatment *does* lead to this simple result.

In calculating the average duration of a collision, we have now to allow for the motion of the centres of the second set, that is for the motion of the centre of the sphere of radius  $\sigma$ , or what comes to the same thing, for the motion of the starting-point on its surface. The probability of a particular radial displacement of the starting-point is given by a distribution function of the same form as that used for the motion of the centres of the first set, but with  $D_1$  replaced by  $D_2$ .  $\tau'$  will now be given by the same integral as before, but with  $q(t)$  appropriately averaged. This must be done by taking the number of centres of the first set which are within the sphere of radius  $\sigma$  when the starting-point has suffered a given displacement, multiplying by the probability of the displacement, and integrating over all possible displacements. A detailed integration has been carried out along these lines, and leads to the conclusion already stated. It will, however, not be given here, since it is lengthy, and since the same conclusion can be reached by the following general argument.

It is clear that the integral for  $\tau'$  is correctly modified to allow for the motion of the starting-point if instead of expressing it in terms of the probability of a given displacement of a centre of the first set relative to a fixed origin, we use the probability of a given displacement of a centre of the first set relative to a centre of the second. It was proved by Smoluchowski<sup>1</sup> as part of his own treatment that this probability is given by a formula which is the same as the one originally used except for the substitution of  $D_1 + D_2$  for  $D_1$ . This substitution will lead to the same change in the formula for  $\tau'$ , so the general collision frequency will be  $\nu' = 4\pi n_1 n_2 \sigma (D_1 + D_2)$ .

### Summary and Conclusions.

It has been shown that whereas the criticisms advanced elsewhere by the author against the theoretical treatment of Smoluchowski remain justified, an exact treatment leads to precisely the same formulæ, thus contradicting the indications of the author's previous approximate treatment. It follows that the theory of the effect of heterogeneity given by Smoluchowski requires no modification.

The theory, however, is only applicable to spherical particles coagulating to give spherical particles, and as pointed out in the author's previous paper, a departure from these conditions must lead to a marked change in the coagulation coefficient. The agreement between the calculated rate of coagulation for particles which coalesce on coagulation so as to form new spherical particles, and the observed rate for oleic acid smokes, must now be taken as showing that the different cohesive forces for different orientations of the long chain compound do not have the result of deforming the droplets appreciably from the spherical shape, and that even if an adsorbed surface layer does prevent true coalescence on coagulation, yet the resultant complex droplet is deformed into a shape which is nearly spherical. The further agreement with the observed rate of coagulation of stearic acid smokes must be taken as showing that the stearic acid is a super-cooled liquid in the early stages of the coagulation, even though it is solid in the later stages. It is unfortunate that experimental evidence is not available to check these conclusions directly.

University of Bristol.*

## GENERAL DISCUSSION.\*

**Professor R. Whytlaw-Gray** (*Leeds*) said: Experimental evidence suggests that the rate of coagulation is not greatly influenced by the shape of the particles. The constants for smokes of stearic and oleic acids agree closely with theory whilst that for ferric oxide of the same weight concentration is only 30 per cent. greater. When these smokes are allowed to coagulate until the particles are large enough to be seen with the microscope, the stearic acid complexes, though not truly spherical, are of a compact form, whilst those of ferric oxide are loosely built, chain-like structures, formed of units which appear like beads on curly strings.

The difference in structure of the two types is striking and if the ultramicroscopic particles possess the same form as those of microscopic dimensions, it is surprising that the coagulation constants for the two smokes do not show a greater divergence.

It is therefore evident either that the form of the particles has a relatively small effect on the coagulation rate, or that the ultramicroscopic particles even in a smoke like ferric oxide, with such a marked tendency to chain formation, are spherical in the early stages. Examination by X-ray or electron diffraction methods might enable the size of the units in these aggregates to be estimated and thus throw light on this question.

**Mr. W. Barrett** (*Gerrard's Cross*) said: In the equation  $dn/dt = -Kn^2$ ,  $K$  has the dimensions of (frequency)  $\times$  (volume). This suggests that there may be a fundamental frequency, but nothing of the kind seems to appear. For purposes of extrapolation it would seem preferable to use the form  $dn/dt = -Kn(n - 1/V)$  where  $V$  is the volume occupied by the smoke. The integral of this is

$$\frac{1}{nV} = 1 - e^{-\frac{Kt}{V}}$$

which does not, as the classical equation, lead to a value less than unity for the total number of particles at the end of infinite time. The curve is tangential to  $1/n = Kt$  at the origin and asymptotic to  $nV = 1$  at infinity.

**Professor J. C. Philip** (*London*) said: Is it not possible that the gap between the molecular state and that of the "primary particles" is associated with the high curvature of extremely small droplets (particles) and the correspondingly high vapour pressure?

**Mr. A. G. Grant** (*communicated*): Dr. Fuchs' paper is the only one in this section applying specifically to electrical precipitation phenomena, and I have endeavoured to compare the authors' results with values obtaining in full scale plant working.

The charging of a particle in an electric field is in effect the collection of electronic charges up to a saturation value determined by the dielectric constant and radius of the particle and the strength of the field. Millikan in his Oil Drop Apparatus has demonstrated that in a feebly ionised field, the rate of electron charge collection is relatively small, and in fact he was able to study the successive addition of small numbers of electrons.

In the more strongly ionised fields obtaining in electrical precipitation, it has generally been assumed that a particle acquires its saturation charge in negligible time, this charge being given by the first half of expression (1) in the authors' paper. The authors have now demonstrated that a measurable time is required to reach saturation in accordance with the correction applied by the expression  $\frac{\pi unet}{1 + \pi unet}$ .

In their experiments only 30 per cent. of the maximum charge was reached in the measurable time of approximately 0.02 seconds. It is to be regretted that they were not able to make determinations and to plot

\* On the three preceding papers.

results for a wider range of times, as their work resolves itself into a single point determination—that is, we now know only that expression (1) is correct for complete saturation when the value of time is relatively great, and for partial saturation at the one time, 0.02 seconds. Nevertheless we can probably assume the validity of the time correction.

Now, whilst in precipitation work, values vary over a wide range, I think we can take, as typical lower values, a field strength of a thousand volts per centimetre, and an ion concentration of  $10^8$  per c.c. These figures are respectively twice and ten times those used by the authors. We can retain their particle radius of the order  $\mu$ . Inserting these values in their expression for particle charge, we obtain altogether higher degrees of charging. For times of 0.5 seconds upwards, the departure from saturation is negligible. At 0.05 seconds the degree of saturation is 80 per cent.

In precipitation work, I think we can say that 0.5 seconds is the lower limit for time of contact of a particle in the ionising field. In this time and for values I have just assumed, 97.5 per cent. of the maximum charge is acquired by the particle. It thus appears that the authors' work in establishing the validity of the time correction has enabled us to show that in ordinary precipitation work the time factor can be ignored; that the earlier assumption, though without justification, that precipitation calculations can be made on the basis of a fully charged particle, was in fact correct.

I think an explanation is easy to find. The velocity of a particle in the electric field varies directly as its charge, so that a 50 per cent. charged particle will be precipitated in double the time required by a fully charged one. Thus time for removal is a function of charge, and charge is a function of time. Now since removal time is large, compared with the required charging time, it automatically follows that a field so designed as to remove the particle, will automatically give it its saturation charge.

This paper is of very great practical value as being, to my knowledge, the first successful attempt to determine the time factor under controlled conditions, and I hope that my remarks will not be taken by the authors to imply that their work has been other than constructive.

**Dr. N. Fuchs (Moscow) (communicated):** I cannot agree with the objections to the theoretical treatment of coagulation given by Smoluchowski which are put forward by Mr. Harper. The deduction of Smoluchowski can be presented in a form which does not require the explicit use of a "concentration gradient," attacked by Mr. Harper, and approaches the treatment given by Mr. Harper himself.

Let  $W(x, y, z, t)$  be the probability that a material point with co-ordinates  $x, y, z$ , performing the Brownian movement will cross a certain immovable surface at least once during time  $t$ . Kholmogoroff<sup>1</sup> showed that  $W$  must satisfy the Einstein-Fokker equation

$$\frac{\partial W}{\partial t} = D \Delta W. \quad (1)$$

In the case of a spherical surface with radius  $\sigma$ ,  $W$  depends only on the distance  $r$  between the material point and the centre of the sphere, and equation (1) takes the form

$$\frac{\partial W}{\partial t} = D \left( \frac{2}{r} \frac{\partial W}{\partial r} + \frac{\partial^2 W}{\partial r^2} \right). \quad (2)$$

From the physical significance of  $W(r, t)$  it is clear that  $W(\sigma, t) = 1$  when  $t > 0$ , and  $W(r, 0) = 0$  when  $r > \sigma$ . The solution of (2) is therefore:

$$W(r, t) = \frac{\sigma}{r} - \frac{2\sigma}{r\sqrt{\pi}} \int_0^{\frac{r-\sigma}{2\sqrt{Dt}}} e^{-z^2} dz. \quad (3)$$

<sup>1</sup> Kholmogoroff and Leontowitch, *Physik. Z. Sowjetunion*, 1933, 4, 1.

We have thus obtained an expression for the probability that a material point (whose distance from the centre of a sphere  $\sigma$  is  $r$ ) will cross its surface at least once in time  $t$ . If at the moment  $t = 0$  the spheres  $\sigma$  are distributed at random with the mean concentration  $n$ , there will be  $4\pi r^2 n dr$  of them within a spherical shell defined by  $r$  and  $r + dr$ , whose centre is the initial position of the material point, and the point will cross in time  $t$  the surface of as many as

$$dI = 4\pi W(r, t) nr^2 dr$$

spheres.

The total number of the spheres crossed will be :

$$I = 4\pi n \int_{\sigma}^{\infty} W(r, t) r^2 dr. \quad . \quad . \quad . \quad (4)$$

In unit time it gives

$$\frac{dI}{dt} = 4\pi n D \left( 1 + \frac{\sigma}{\sqrt{\pi D t}} \right) . \quad . \quad . \quad . \quad (5)$$

and that is exactly the equation obtained by Smoluchowski. It differs from that deduced by Harper by the factor  $1 + \frac{\sigma}{\sqrt{\pi D t}}$ , which rapidly approaches unity. The physical significance of this factor is obvious : in our deduction we counted only the spheres crossed by the material point the first time, and did not pay any attention to the subsequent crossings of the same sphere. At the beginning of the process the point is surrounded by those spheres which it has not yet crossed and, therefore, the number of registered crossings in unit time is larger than later on, when a certain stationary distribution of spheres, which have already been crossed, is established around the point. In the treatment given by Harper which is based on averaging the time spent by the material point within a single sphere this circumstance is omitted.

The deduction cited above shows that the theory of coagulation given by Smoluchowski is correct in all cases where equation (1) is valid, *i.e.* when the radius of the particles is large in comparison with their "apparent mean free path."<sup>3</sup> If this condition is not satisfied, a correction for the "concentration drop" at the surface of the spheres  $\sigma$ , diminishing the rate of coagulation, must be introduced in the equation (5). This drop is quite similar to the well-known temperature-drop and velocity-drop (slip) at the surface of small spheres in gaseous media, and was taken into account for the first time by Townsend<sup>3</sup> in his theory of diffusion of ions towards small conducting spheres. For particles of  $10^{-5}$  cm. radius this correction makes a difference of only few per cent., but for  $10^{-6}$  cm. particles it is already very considerable.<sup>4</sup>

In reply to Mr. Grant (*communicated*): I must emphasise, that our work is substantially a further development of the excellent work of M. Pauthenier and co-workers cited in our paper.

The chief result obtained in our laboratory is that the charging-equation derived and experimentally tested by Pauthenier over a wide range of time remains exactly valid for small particles. Although this result was obtained for a small range of time (0.01-0.02 sec.) only, there remains little doubt as to its applicability over the whole range of the charging.

On the other hand it seems that the applicability of Pauthenier's equation to small particles ( $\sim 1\mu$ ) is limited to comparatively large values of the field-strength as used in electric precipitators. In a weak field the effect due to the diffusion of ions can by no means be neglected.

<sup>3</sup> Smoluchowski, *Annal. Physik.*, 1906, **21**, 769.

<sup>3</sup> Townsend, *Electricity in Gases*, Chapter 6, 1915.

<sup>4</sup> Fuchs, *Z. physik. Chem.*, 1934, **171**, 199.

**Dr. W. R. Harper** (*Bristol*), in reply (*communicated*): I may appear to be excessively insistent on mathematical rigour, but there is good reason for it. In developing my own treatment a certain step in the argument seemed mathematically obvious not merely to myself but to others whom I consulted. Moreover there was a proof to justify it. Nevertheless it subsequently appeared that the proof was faulty and that what had seemed obvious required changing by a factor of two. I conclude that the result of any treatment is only to be trusted when obtained by flawless reasoning.

Doubts of this nature concerning the treatment of Dr. Fuchs restrained me from taking the initiative in discussing it, but I would now say that his treatment seems to me to be perfectly rigid with one proviso and one exception. The proviso is that the treatment be presented as a calculation of the collision frequency in a system of interpenetrating spheres as in my own treatment, and subsequently applied to the actual coagulation problem with the justification therein given. We can then choose one centre out of the system and follow its track from  $t = 0$  to  $t = \infty$ , calculating how many spheres it intersects per second, and avoid having to picture it as possessing the incompatible properties of being able to collide with a number of spheres without changing its identity, and becoming a different particle after each collision. It is ensured that multiple collisions are counted as single by working with the probability that each surface is crossed at least once, and by neglecting the initial part of the solution. A comparison of the initial form with the ultimate form of the solution now shows that the multiplicity of a collision must be infinite, it being presupposed however that the mean free path of the centre is infinitesimally small, its track velocity being of course infinite to give a finite diffusion coefficient.

The apparently innocent assumption that  $W(\sigma, t) = 1$  for  $t > 0$  appears to me to require proof, and this is not given in the work of Kholmogoroff referred to. For it to be correct, a centre starting infinitely near a plane surface cannot move to a finite distance from the surface without crossing it at least once, and it would seem pre-supposed that the mean free path is to be taken as an infinitesimal of the second order, since we are considering Brownian motion and not a phenomenon dependent on track velocity. We may magnify the picture and conclude that the assumption is only correct if a centre starting at a finite distance from an infinite plane surface and executing Brownian motion with an infinitesimally small mean free path cannot move to infinity without crossing the surface. Whether or not this is so, seems to me to be by no means obvious, but it must be so since Dr. Fuchs and I obtain the same value for the coagulation coefficient.

I cannot admit that the treatment of Dr. Fuchs disposes of my objections to the treatment of Smoluchowski—I would say rather that it avoids them. It is difficult to decide from the original papers of Smoluchowski just what significance he intended to be attached to his mathematics, but from the formulation in the *Zeitschrift für Physikalische Chemie*, it seems clear that the colloid particle is to be regarded as analogous to a large sphere on which particles of vapour are being condensed, in which case the objection that the colloid particle has coagulated before even the establishment of the boundary conditions which lead to the solution of the problem for the large sphere can be made precise, and is surely valid. I now see however that this objection and others can most simply be met by again presenting the mathematics as a derivation of the collision frequency for a system of interpenetrating spheres and then applying the result to coagulation with the appropriate justification, instead of presenting it as a direct calculation of the rate of coagulation. We choose one sphere out of the system at time  $t = 0$ , and calculate for all subsequent time how many centres cross its surface per second for the first time. This clearly gives the collision frequency for the sphere if multiple collisions are counted as single collisions, except that the initial part of the solution must again be neglected because we are then counting some collisions which really belong to

time previous to  $t = 0$ . Smoluchowski's method of calculating the number of first arrivals is of course to solve the diffusion equation with the appropriate initial conditions and the boundary condition of zero concentration. He justifies this on the ground that it works for the particular case of a plane surface, from which one may conclude that he regarded it as plausible but unproven that it is correct in the general case. It may however be proved in the following way: Consider any initial distribution of centres in space situated on one side of any closed surface. It is required to find the mean number of centres that will have crossed the surface at least once in time  $t$ . This is equal to the number that would have been removed from the distribution if the surface annihilated them on arrival. The annihilation may be carried out by creating a negative centre when and where a (positive) centre arrives at the surface, but otherwise allowing both sets of centres to diffuse unimpeded by the surface. The distribution of both positive and negative centres is governed by the diffusion equation, so the actual distribution of centres (with annihilation at the surface), being the difference between these distributions, is also a solution of the diffusion equation. That it is the solution with concentration at the surface put equal to zero follows from the fact that if it were not, there would be maintained a concentration discontinuity at the surface (the concentration inside being *ex hypothesi* zero), which would result in an infinite rate of removal of centres from the distribution, and this could not be maintained.

The treatment of Smoluchowski can therefore be presented in a mathematically rigorous form leading to the usual result. It can, moreover, be transformed into my own formulation, thus providing a cross check. We may therefore conclude that there is now no doubt whatsoever about the value of the coagulation coefficient.

---

## INTRODUCTORY PAPER, PART I.(b) THE GENERAL PROPERTIES AND BEHAVIOUR OF DISPERSE SYSTEMS CONSISTING OF AQUEOUS AND OTHER VOLATILE PARTICLES, *i.e.* MIST, CLOUD, HYGROSCOPIC NUCLEI, TOWN AND COUNTRY FOGS.

BY G. M. B. DOBSON.

*Received 13th March, 1936.*

### Meteorological Aspects.

I have been asked by the Council to give a short introductory talk on the meteorological aspects of Dust, Smoke, and Fog. I think that it will be best if I try to give a very brief résumé of our knowledge of this subject at the present time, and thereby to reveal where our ignorance is greatest and where more work is particularly wanted.

With regard to atmospheric haze and fog—whether in country or town—the main physical principles appear to be known, but there is much that requires further elucidation. In clear air, free from fog, there are always present a large number of minute particles, some of which are hygroscopic, while others are not so. In country districts, particularly near the sea, the hygroscopic particles may be largely sea salt derived from sea spray, while in towns, those due to combustion of fuel, such as droplets of  $\text{H}_2\text{SO}_4$ , will probably outnumber the others.

It has been suggested that nuclei are formed by sunlight, but this does not seem to be certain.

These hygroscopic particles will condense upon themselves an amount of water depending on the relative humidity of the surrounding air, until they are in equilibrium and their vapour pressure is equal to that in the air. Their size will thus vary with the relative humidity, while their number remains constant. Thus the visibility will depend on the relative humidity as was shown by Aitken. On the other hand, the non-hygroscopic particles will remain constant in size and add an amount to the haziness which is independent of relative humidity.

Many of these minute particles can be seen in the ultra-microscope (possibly all, if the illumination be good enough), and if arrangements be made to saturate the air and cool it by a slight expansion, the condensation of water upon them is immediately seen. The particles are clearly of all sizes, and so far as I have seen, most of them seem to have water condensed on them at a supersaturation of 1 or 2 per cent. forming droplets. An estimate of the size of individual particles can be made from the magnitude of their Brownian motion. The particles appear to have a radius of a few times  $10^{-6}$  cm. The smaller particles therefore scatter light to an extent which depends on the inverse fourth power of the wave-length of the light and on the sixth power of the radius of the scattering particle. (Owing to this sixth power law, the smallest particles are very difficult to see in the ultra-microscope and, judging by the brightness, the particles appear to vary in size more than they really do.) On the other hand, the larger particles scatter all wave-lengths alike, hence the increasing whiteness of the sky in hazy conditions.

When the humidity approaches saturation, a large amount of water will condense on the hygroscopic particles, their equilibrium being governed by the opposing effects of surface tension and osmotic pressure. If these two alone determine the size of the drop, it must pass through an unstable size, and as the relative humidity increases, it would slowly grow, and at some point suddenly jump to a much bigger diameter. There are, however, two other things of which we must take account, firstly the removal of water vapour from the air by condensation on the drop, and secondly the effect of latent heat of water. It can be shown that if the initial hygroscopic particles are sufficiently large and numerous, the effect of the removal of water vapour may prevent any unstable growth, while the effect of the latent heat set free, must tend to prevent any sudden condensation.

That only a small number of the original nuclei grow into fog droplets during a fog, is easily seen in the ultramicroscope, where the relatively large fog droplets are seen like brilliant stars falling across the field of view, and at the same time a far larger number of the minute particles are seen, such as are present when there is no fog. This, of course, is what theory would lead us to expect, as the largest hygroscopic particles would first grow into fog droplets, and, only after these were removed, would the smaller particles increase greatly in size. This should make us reflect whether we are making the best observations for meteorological purposes if we measure the total number of hygroscopic particles present in the air as we do with the Aitken Counter. Should we get a more useful measure for meteorological purposes if we counted only the number of particles which condensed water sufficiently easily to form nuclei for fog and rain drops? This number is probably much smaller than the number counted by the Aitken apparatus. The difficulty

would be that there are probably particles of all types present in any sample of air, forming a continuous series, and we should have to draw some arbitrary line between those that readily act as condensation centres, and those which require some considerable supersaturation.

It is clear that the relative humidity must be approximately 100 per cent. in a fog, but it is not certain whether it may be a little above or below this value. From the effect of surface tension we should expect it to be slightly above 100 per cent. but it seems possible that the droplets and nuclei may be cooled by radiations slightly below the temperature of the surrounding air, so that they will be in equilibrium at a relative humidity slightly below 100 per cent.

The processes taking place after the fog has formed, are not entirely clear. If the hygroscopic nuclei are of such a size that there is an unstable period in their growth, and if cooling continues slowly in air already at 100 per cent. R.H., one would expect the excess water vapour to condense out on the existing droplets, so that these would increase in size, but there would be little increase in the number of droplets, unless those initially formed had fallen out of the air. On the other hand, if the hygroscopic nuclei are so large and numerous that there is no unstable period in their growth, the larger ones might become stable, and condensation occur on those slightly smaller. Which of these represents the facts in nature I do not know, possibly one in clean country air, and the other in towns. Certainly as a fog gets thicker, the number of droplets appears to increase.

It has been stated that the sizes of fog droplets fall into definite groups, so that those of one group may be explained as due to the combination of two drops of a group with smaller size. Again measurements have been given showing that while drops of all sizes within a wide range are present in any fog, there is in any given fog a particular radius which is most common, and that this radius is always a whole multiple of a certain value. Before the meteorological world will accept any of these views, they will clearly require many more observations.

The fog droplets being of the order of a few microns in radius, scatter all wave-lengths of light alike, hence the sun seen through a country fog appears white, and it is only in a town fog where there may be a large number of minute particles in addition to the water droplets, that the sun may appear red in a fog. This shows that the benefit to be expected from coloured lights when driving in a fog is negligible.

It seems probable that electrical conditions have no appreciable effect on the equilibrium of fog particles. That mobile ions are caught on the fog droplets is well known, the conductivity of the air thereby being greatly reduced, causing the great increase in the electric potential gradient usually observed in a fog.

The conditions when a fog evaporates, will be largely the reverse of those when it forms, except for two things. Firstly as we have already said, the temperature of the particle may not be exactly that of the surrounding air, and secondly, in towns, the solution of  $\text{SO}_2$  in the fog droplets and its slow oxidation into  $\text{SO}_3$  may lead to the evaporating droplet being a dilute solution of  $\text{H}_2\text{SO}_4$  when the droplet will be stable at a lower relative humidity than that at which it was formed. There seem to be few observations to guide us here.

I would call the attention of workers in this field to the value of observations made with ultra-microscopic methods. These may be made either in small glass cells as described by Professor Whytelaw-Gray or,

for use in the free air, they may be much larger. It is quite possible to arrange an intense beam of light with suitable diaphragms, so that the light scattered from the beam by pure dust-free air can be seen. In such an apparatus the small particles present in non-foggy air are seen and their rate of growth with increasing relative humidity can be studied. The advent of the new high pressure mercury vapour lamp shortly to be placed on the market, should make the ultra-microscopic method of much greater value still. A great advantage of the ultra-microscopic method is that the particles and droplets are studied with the minimum of alteration from their natural conditions, and each particle can be dealt with separately, without making any assumption that all particles are alike.

Passing to the removal of particulate matter from the atmosphere, presumably washing out by rain, plays a large part, but our knowledge is very scanty indeed. For instance, is the removal due to the washing action of rain as it falls through the atmosphere or is most of the particulate matter brought down by rain caught at the moment of condensation within the cloud?

We are equally ignorant about the distribution of particulate matter. Thus, how does the pollution produced by a town fall off with distance from the town, under different conditions?

Finally, what is the effect of particulate matter in the atmosphere in cutting off sunlight and daylight? Particularly what is its effect within large cities? Is the decrease of light approximately the same for all wave-lengths, or are there sufficient very small particles in city air to make the reduction of the short wave-lengths much greater than that of the long wave-lengths? Measurements have shown that ultra-violet light may be reduced at the centre of a town, to half the intensity of that received in the suburbs, but such measurements are unfortunately few, and these frequently refer to one band of wave-lengths only.

The discussion of these matters now to take place, is certain to be of great interest, and I hope, will act as a stimulus to still further work on the subject, which is really one of extraordinary importance to the community as a whole.

## THE NUCLEUS IN AND THE GROWTH OF HYGROSCOPIC DROPLETS.

BY HILDING KÖHLER (*Uppsala*).

*Received 6th April, 1936.*

The nature of the nuclei of which a cloud is really formed can best be investigated through the droplets of which the cloud is composed. Such an investigation generally presents great difficulty. After long microscopic investigations I proved that the ice which, in fog, is deposited on mountains as frost is formed through the undercooling of water droplets. The difficulties have thus been reduced to an analysis of such masses of ice.

Since the investigations of Melander and Lüdeling it has been sup-

posed that sea-salts can serve as nuclei of cloud condensation ; that this must be the case has recently been proved by J. H. Coste and H. L. Wright.

From 1919 to 1923 (independently of earlier suppositions) I carried out (on the Haldde) analyses of hoar-frost for chlorine content, on the supposition that sea salts were nuclei of cloud condensation, and at the same time measured the size of the droplets in the fog from which it was deposited.

**A. Chlorine.**—Generally about 2 kg. of hoar-frost, collected with precautions against contamination, were evaporated to 100 c.c., and the chlorine content determined by Mohr's method of titration.

**B. The size of the droplets in fogs or clouds** was measured optically. A projector with an arc-lamp and a parabolic mirror sent parallel rays to the observer 61·8 m. away. The coronæ in the space-grating formed by the droplets were measured. From the radius of these coronæ the radii of the droplets were measured according to the well-known formulæ :—

$$r = \frac{1 \cdot 220 \cdot \lambda}{2 \sin \theta_1} ; r = \frac{2 \cdot 233 \cdot \lambda}{2 \sin \theta_2} ; r = \frac{3 \cdot 238 \cdot \lambda}{2 \sin \theta_3},$$

where  $\theta$  is the angular radius of the first ( $\theta_1$ ), second ( $\theta_2$ ) and third ( $\theta_3$ ) coronæ, measured at the outer line of the violet colours, and  $\lambda$  is the so-called "wave-length of white light" ( $0 \cdot 571 \mu$ ). The clearness of the coronæ depends on the homogeneity of the cloud. If a certain size of droplets sufficiently outnumbered all others we get measurable coronæ. The more homogeneous the cloud, the clearer are the coronæ, the more distinct the limits ; with a preponderance of drops of a certain size very distinct limits are observed.

Lichen spores were used to give frequency curves of different standard degrees of deviation grouped around an average size. Measurements of the coronæ given by these spore clouds showed that the spores had dimensions which corresponded with a great accuracy with the average values microscopically measured.<sup>1</sup> If the standard deviation was great (as for instance in the case of purchased Lycopodium spores), the coronæ became pale and indistinct, since the white colour is dispersed over the different colours, although even in this case the measurements of coronæ gave the size of those spores which are present in the greatest quantity.

*By measurements of coronæ in fogs there is thus obtained, the size of those droplets which are in the majority within the field of observation.* If very dissimilar droplets are present to the same extent the coronæ become very indistinct ; according to my experience this is often the case with low-land fogs, and sometimes occurs also in clouds and mountain fogs. No coronæ at all may arise, if the fog is sufficiently inhomogeneous and no one size preponderates. A single well-performed measurement of coronæ gives a more reliable value than several millions of measurements of separate droplets.

## Results.

1. The most commonly occurring chlorine content was about 3·5 mgm. per litre of melted ice. It is very remarkable that other concentrations could, within the limits of error, be written  $3 \cdot 595 \times 2^p$ , where  $p$  is a whole number, positive or negative. The highest and lowest concentrations were 56·33 and about 0·067 mgm. per litre respectively ; although the latter value is uncertain on account of the large experimental errors (amounting

Svenska Vetenskapsakademien, 24A, No. 9.

to 50 per cent.) at such low concentrations. On the presumption that all sea salts are present we get the concentration of these salts per litre of melted ice (according to Knudsen) on multiplication by 1.805.

H. Israël<sup>2</sup> has found almost the same proportion of chlorine in rain, *viz.*, 3.42 mgm., and, thus,  $3.42 \times 2^2$ . The fact that the concentration of chlorine in rain-drops diverges only very slightly from the concentration of the droplets in fogs and clouds, the mass of which is about a million times smaller, is of great importance.

Analyses of chlorine content in rain-water carried out over the period 1870-86 by Kinch,<sup>3</sup> gave the following results:—

Average of 16 years, 3.81 mgm. per litre.

" " 12 " 3.36 mgm. per litre.

*There is therefore no essential difference between the concentration of chlorine in the rain-drops and in the fogs on the level of the Haldde.*

On the other hand, my own analyses on the Sonnblick, and similar analyses by Lipp and Lauscher on the Zugspitze and the Sonnblick,<sup>4</sup> have shown that the concentration of chlorine in fogs decreases with the height. Rain generally falls from clouds lying at about the level of the Haldde (914 metres above sea-level). We shall explain later the reason of this decrease of the concentration of chlorine with the height above sea-level.

2. The measurements of the droplets gave an average size of  $r = 8.86\mu$ . According to theoretical investigations,<sup>1</sup> supported by the experimental observations of L. F. Richardson,<sup>5</sup> a systematic error of, at most, 4 per cent. may attach to this value. Sometimes the size of the droplets changed unduly during a series of measures, and frequently the average value varied from series to series. When frequency curves were drawn for the series of measurements there were always, however, maxima at certain droplet sizes. The relation between those radii which gave these maxima could be expressed as  $r = B \cdot 2^{n/3}\mu$  ( $B = 8.82$ ), where  $n$  had whole (either, positive or negative) values. I therefore, for all separate measurements, calculated  $n$  also. This value (8.82) of  $B$  was obtained direct from the frequency curves. Frequency curves of  $n$  were drawn for all the measured series and from these it was clear that there is only one maximum, so long as the standard deviation of  $n$  is less than or equal to 0.19. With few exceptions these maxima were in the neighbourhood of values of whole numbers of  $n$  (or more exactly  $n \pm 0.019 \pm 0.0050$ ). There further appeared such single series as  $n \pm 0.426 \pm 0.0134$ . Frequency curves with a greater standard deviation always showed maxima close to these values of  $n$ , although the radii of the droplets often varied from  $3\mu$  to  $25\mu$ .

I therefore made statistical examination, partly to examine the reality of these maxima, and partly to calculate more exactly the values of  $n$ . *Thus this work was not carried out in order to prove any particular hypothesis. I have never made any hypothesis of the size distribution of the droplets.* The separate measurements in the single series ( $\sigma < 0.19$ ) grouped themselves round the average values of the whole numbers of  $n$  (or  $n \pm 0.445 \pm 0.0070$ ) according to normal curves with  $\sigma = 0.173$ . This standard deviation is greater than that of the errors of measurement, which is on an average  $\sigma = 0.053$  ( $\sigma = 0.131$  for  $n = 6$ , to  $0.029$  for  $n = -5$ ).

*Hence it follows that the size of droplets present in preponderating proportions in the clouds changes, and that other sizes are found than those which give the maximal frequency.*

Series including 2 to 4 maxima were also statistically worked out, and it was found that even these gave normal curves. We then calculated  $A_3$  (the measurements grouped round the whole  $n$ , which we now call the

<sup>5</sup> "The Brown Corona and the Diameter of Particles," *Quart. J. Roy. Meteor. Soc.*, 1925, 51, 1.

3-group), and  $A_2$  (the measurements round  $n + 0.445$ , which we now call the 2-group). The figures for  $n$  and  $\sigma$  and the relative number  $A$ , expressed as a percentage of the number of measurements, were :—

<i>The 3-group.</i>	<i>The 2-group.</i>
$n : n + 0.018 \pm 0.0053$	$n + 0.452 \pm 0.0081$
$A : 62.7$ per cent.	$37.3$ per cent.
$\sigma :$	$0.177$ for both groups.

From all these measurements (which contained series with up to 15 maxima), we calculated by another method the percentage distribution, viz. :—

<i>The 3-group.</i>	<i>The 2-group.</i>
$60.4$ per cent.	$39.6$ per cent.

The distribution of the series earlier calculated being :—

<i>The 3-group.</i>	<i>The 2-group.</i>
$61.9$ per cent.	$38.1$ per cent.

The two being in unexpectedly good accordance.

If the masses of the droplets was then calculated, it was found that these could be written in the proportions  $2 : 3 : 4 : 6 : 8 : 12 : 16$  and so on.

In this mass series,  $2 \times 2^n$  corresponds to the droplets in the 2-group and  $3 \times 2^n$  to the droplets in the 3-group. It has later been found that two other groups probably exist, corresponding to the figures 5 and 7 in the above-mentioned mass-series. The complete series can, then, be written :  $2 : 3 : 4 : 5 : 6 : 7 : 8 : 10 : 12 : 14 : 16$  and so on.

These results are empirical and valid for mountain fogs and clouds ; if they are wrong there must be some unknown error in the method of measurement. Recently Niederdorfer<sup>6</sup> has found in rain, by quite another method, the same mass distribution as is given in the above-mentioned series. The results obtained by Findeisen<sup>7</sup> and Hageman<sup>8</sup> are valid for lowland fogs and are obtained through measurements of separate droplets. This method of measurement, which (in regard to droplets in fogs and clouds) has been previously compared with the optical method of measurement, cannot be compared in regard to reliability.

I cannot yet offer any explanation of the classification of the groups of droplets and quantity of chlorine. It has, however, been necessary to give an account of these facts in order to make this description comprehensible.

### The Thermodynamics of the Condensation on Hygroscopic Nuclei.

Taking the average values of  $3.595$  mgm./l. chlorine and radius of droplets  $8.86 \mu$ , we proceed, as in a previous paper,<sup>9</sup> where  $r$  was taken as  $8.82 \mu$ . On the supposition that all sea-salts are present in the nucleus, it is calculated that a nucleus of dry sea-salts has the mass of  $1.847 \times 10^{-14}$  gm. I here take  $10^{-14}$  gm. as mass unit and make  $\alpha_1^3 = 1.847$ . As the quantities of chlorine in the frost are distributed in the proportion  $2^n$ , the masses of the nuclei must also stand in the same relation.

Instead of  $r$  I here use  $n$  as a variable which varies continually. If  $8.82 \mu = 8.82 \times 10^{-4}$  cm.  $= B$ , we then get  $r = B \cdot 2^{n/3}$ .

From this it follows that  $p - n = L$  determines the concentration of the droplet. At a certain value of  $L$  the concentration is invariably independent of  $p$  and  $n$ . Table I gives concentrations expressed in gm. of salt per 1000 gm. of solution at different values of  $L$ .

The total quantity of water in a liquid state in the weight unit of air depends, not only on the concentration of the droplets, but also on the number of nuclei, if every nucleus becomes the centre of a droplet. This number  $N$  is of great importance for the understanding of atmospheric condensations.

We now calculate, in terms of the whole quantity of salt being NaCl (since the chemical constants of this salt are well known), and on the supposition that the same laws apply to the small volumes, with which we are dealing, as apply for larger volumes. Now, a salt in water lowers the vapour-tension, but the latter is higher above a convex than above a plane surface. The specific volume  $v'$  of a droplet with the radius  $B \cdot 2^{n/3}$  and with salt nucleus can be written

$$v' = \frac{1}{1 + \alpha_1^3 \cdot \delta^3 \cdot 2^{p-n}},$$

where  $\delta^3$  is a constant, equal to  $2.483 \times 10^{-6}$ . If NaCl has a constant dissociation of 75 per cent., the vapour tension  $e_i$  above a plane solution surface can be expressed as:—

$$e_i = e_m \frac{1 - \epsilon_a \cdot \alpha_1^3 \cdot 2^{p-n}}{1 - \epsilon_i \cdot \alpha_1^3 \cdot 2^{p-n}},$$

where  $\epsilon_a = 9.930 \times 10^{-7}$ ,  $\epsilon_i = 1.149 \times 10^{-6}$ , and  $e_m$  the pressure of a saturated vapour.

The vapour tension above a droplet of radius  $r = B \cdot 2^{n/3}$  of this solution is:

$$\log e = \log e_i + \frac{2 \cdot s \cdot v'}{R_1 \cdot T \cdot B \cdot 2^{n/3}},$$

where  $R_1$  is equal to the gas constant of the water-vapour (4706.91),

$T$  is the absolute temperature, and

$s$  is the capillarity constant, which is a function of temperature and concentration as follows:—

$$s = s_0(1 - bT) + \frac{c \cdot \alpha_1^3 \cdot 2^{p-n}}{1 - \beta^3 \cdot \alpha_1^3 \cdot 2^{p-n}},$$

where  $s_0 = 1.1683 \times 10^{-1}$ ,

$b = 1.2518 \times 10^{-3}$ ,

$c = 8.4 \times 10^{-8}$ ,

$\beta^3 = 9.960 \times 10^{-7}$ .

In order that a droplet of solution shall remain unchanged in the atmosphere, the vapour tension above it must be equal to the pressure of the vapour in the atmosphere. In Fig. 1 the vapour tension above

droplets at different values of  $\alpha^3$  at different concentrations is shown for  $T = 273$ . It will be seen that the vapour tension first increases with decreasing concentration, passes a maximum and approaches asymptotically the pressure of the saturated vapour. The maxima of the vapour tension become more and more pronounced the smaller  $\alpha^3$  is. If many unequally large nuclei appear in the atmosphere, it follows that on condensation a selection must take place so that, at first, droplets which have been formed on the larger nuclei pass maxima, at which moment droplets on smaller nuclei must evaporate until their vapour tension balances those droplets which have been formed on the larger nuclei. This theoretical result corresponds wholly to the fact that the concentration of Cl in the droplets decreases with the height, as shown by Lauscher and Lipp.<sup>4</sup>

If the sum of the vapour and water absorbed by the hygroscopic nucleus is  $K$ , the solution droplets must have a vapour tension equal to the vapour pressure prevailing in the air; the quantity of vapour  $x$  is calculated from

$$x = K - M \cdot 2^n (1 + \alpha_1^3 \cdot \delta^3 \cdot 2^{-pn}),$$

where

$$M = N \cdot \frac{4}{3} \cdot \pi (8.82)^3 \times 10^{-12}$$

and  $N$  = the number of droplets in 1 gm. of air condensed on the nucleus,  $\alpha_1^3 \cdot 2^p$  and  $\delta^3$  have the same values as before.  $N$  is very large; the larger it is the more quickly  $x$  approaches zero.

The latent heat of condensation  $\lambda$  for the solution droplets can easily be calculated:

$$\lambda = AT \left[ R_1 T \frac{\partial \log e}{\partial T} + \frac{\partial e}{\partial T} \cdot \frac{\partial v'}{\partial x} (K - x) - R_1 x \frac{\partial \log e}{\partial x} \right],$$

where  $A$  is Joule's equivalent. The middle term in the brackets can be neglected in comparison with the others. From Clapeyron's formula for the latent heat of evaporation of water,

$$\lambda_0 = A \cdot R_1 T^2 \frac{\partial \log e}{\partial T},$$

we get:—

$$\lambda = \lambda_0 + \frac{2 \cdot A \cdot T^2 \cdot v'}{B \cdot 2^{n/3}} \cdot \frac{\partial}{\partial T} \left( \frac{s}{T} \right) - A \cdot R_1 \cdot T \cdot x \frac{\partial \log e}{\partial x}.$$

In this expression the second term is always negative. The third term is negative, if  $e$  increases with decreasing  $x$ , which is the case before the maximum of vapour tension has been reached (see Fig. 1); this term is greater than the second, so that within this interval

$$\lambda > \lambda_0.$$

After the maximum has been reached, the third term is positive but, since the second term is always negative, it follows that within this interval

$$\lambda < \lambda_0.$$

Without detailing the calculations we can now see how far the droplets increase on nuclei (which we regard as droplets of a more or less concentrated solution of salt) if a quantity of air is adiabatically cooled.

If a quantity of heat  $q$  is added to the system of droplets-water-vapour, this heat is used partly in heating the system and partly in evaporation of droplets, according to the formula

$$q = CdT + \lambda dx.$$

When the entropy is a whole differential we get

$$C = T \int \frac{\partial}{\partial T} \left( \frac{\lambda}{T} \right) dx + F(T),$$

where  $F(T) = K$  or the whole quantity of water of the system, so long as the specific heat of water is regarded as independent of the temperature and equal to unity.

We write the change of entropy

$$\int \frac{q}{T} = \int \frac{C}{T} dT + \int \frac{\lambda}{T} dx + \text{const.} = S(nT) + \text{const.}$$

Fig. 1.

If these processes take place in the atmosphere, the corresponding expression for the changes in the air must be added to this equation :—

$$\int \frac{q}{T} = c_p \log T - AR \log (P - e) + \text{const.}$$

where  $P$  = total atmosphere pressure and  $c_p$  = specific heat of dry air at constant pressure.

Treating the laws of Boyle-Mariotte-Gay Lussacs as valid for both water-vapour and air we get, if the specific volume of the air is  $v_1$  :—

$$P = \frac{RT}{v_1} - e; \quad e = x \cdot \frac{R_1 T}{v_1}$$

from which it follows :—

$$\log (P - e) = \log \frac{R}{R_1} + \log e - \log x.$$

Through the setting-up and combination of the two systems we get finally :—

$$\int \frac{q}{T} = S(nT) + c_p \log T - AR \log e - AR \log \frac{R}{R_1} - AR \log x + \text{const.},$$

where  $e$  is both the partial pressure of water-vapour in the air and the vapour tension of the droplets. The variation of  $e_m$  with temperature is obtained according to the formula :—

$$e_m = 60.49228 - \frac{7027.20766}{T} - 5.8691014 \log T.$$

If the system works under adiabatic conditions  $\int \frac{q}{T} = 0$ . The constant is determined by the initial conditions. The value of  $N$ , which states the number of particles per gm. of dry air is of great importance

to the calculations, as also is the choice of  $\alpha^3$ . We have chosen  $N$  in the following way :  $N_1$  is the number of particles if  $\alpha^3 = \alpha_1^3$ . Then,  $N = N_1 \times 2^p$  if  $\alpha^3 = \alpha_1^3 \times 2^{-p}$  and  $N_1 = 2 \times 10^6$  corresponds to 258.6 nuclei per c.c. of air, a very small number which may be increased a hundred or a thousand-fold. The first fundamental question may be formulated as follows: Why is the number of droplets in fogs so much smaller than the number often measured with Aitkens' Nucleus Counter ?

FIG. 2.

I : $\alpha^3 = \alpha_1^3 \cdot 2^{-9}$	$N = 10^6 \cdot 2^{10}$ per gm. of air
II : $\alpha^3 = \alpha_1^3 \cdot 2^{-4}$	$N = 10^6 \cdot 2^7$ " " " "
III : $\alpha^3 = \alpha_1^3 \cdot 2^{-3}$	$N = 10^6 \cdot 2^4$ " " " "

Fig. 2 shows how the droplets increase (assuming continued condensation) if the initial concentration is expressed by  $p - n = 17$ , and  $N$  has the values shown, the initial temperature being 273 and  $P - e$  being initially 760 mm. The first part of the curve is uncertain as not all the NaCl is dissolved until at about  $p - n = 15.3$ . Thus for  $p = -3$ ,  $n = -18.3$ . The increase is shown in Fig. 3 for the initial temperature  $T = 283$ . In both figures  $n$  is abscissa and  $T - 273$  ordinate, and the atmospheric pressures are also shown.

It will be seen that the increase occurs very rapidly after that the maximal vapour-pressure has been reached. Further, the size of droplets at a certain temperature decreases with  $N$ . We cannot see so clearly that, after having reached a certain size, the size of the droplets can

no longer be doubled through continued condensation. We have referred to the last value of  $n$ , which is obtained through continued condensation as "the last whole  $n$ ." This value varies with  $N$ . The greater  $N$  is, the smaller the whole  $n$  becomes.

FIG. 3.

$$a^2 = a_1^3 \cdot 2^{-6}$$

In Table II are expressed the values of the last whole  $n$ , the concentration of chlorine in these droplets and the temperature  $T$  which this  $n$  reaches if the initial temperature is 273 and the initial concentration can be expressed by  $p - n = 17$ . From this table it follows:—

1. If  $\alpha^3 = \alpha_1^3$  the droplets can, through condensation, change to  $n = +1$ , corresponding to  $r = 11.11 \mu$  if the number of nuclei  $N$  per gm. of dry air is  $2 \times 10^5$ , corresponding to the low number of 258 per c.c. of air at  $0^\circ$  and 760 mm. Through want of vapour the mass of the droplet cannot later on be doubled. If the number of nuclei is  $16 \times 10^5$  per gm. of dry air or 1064 per c.c., the last whole  $n$  cannot on the same nucleus exceed  $-2$ , corresponding to  $r = 5.56 \mu$ . On increasing  $N$  the greatest whole  $n$  decreases, as is seen, to very small figures.

2. *The concentration of chlorine at these last whole  $n$  is that which has in fact been obtained on analysis of hoar-frost.*

3. The greater  $N$  is, the more the air must be cooled before the last whole  $n$  is reached, the higher the air thus must rise, before this  $n$  is reached; thus the concentrations of chlorine due to condensation we have found are reached.

4. The greater  $N$  is, the higher the concentration of chlorine is, when the last whole  $n$  is reached. At a certain value of  $N$  the concentration decreases with  $\alpha^3$ , but the last whole  $n$  remains the same for different  $\alpha^3$ , as long as  $N$  is the same. If the initial temperature  $T$  is 283, the last whole  $n$  is only one unit greater. There is no essential difference in the results obtained, if the initial temperature is varied.

It follows that these solution-droplets, if accompanied by a rising quantity of air, cannot reach the size of raindrops, the masses of which are one or several million times larger than the droplets corresponding to the last whole  $n$  calculated here.

Moreover, the concentration of chlorine in raindrops is the same as in the droplets in fogs and clouds, which are millions of times smaller. From this it follows that raindrops never arise from condensation of the droplets in fogs and clouds; if this were the case the concentration of chlorine must of course be enormously small, on the assumption that chlorine salts are nuclei. Even the droplets in fogs and clouds cannot be obtained through direct condensation, since the concentration of chlorine is independent of the size of the droplets. *The increase must take place so that the concentration remains constant.*

From the circumstance that droplets, formed on different  $\alpha^3$  at different vapour tensions and sizes, pass the maximal vapour tension, it follows that at first larger nuclei come into action and then smaller and smaller. A selection of nuclei takes place. In consequence of this and of the results found in the table, the concentration of chlorine must decrease with the height above sea-level. This has been confirmed by the analyses of Lauscher and Lipp. We conclude finally that the number of droplets in fogs and clouds is much smaller than the number of nuclei obtained in Aitkens' Nucleus Counter. This also points to the fact that increase in dimensions of droplets of any particular size must take place otherwise than through direct condensation. Their size must be independent of the concentration. This increase in number perhaps causes that distribution of groups, of which we have spoken above.

# THE NATURE OF THE DISPERSOIDS IN COUNTRY AND TOWN AIR.

By J. H. COSTE.

*Received 13th March, 1935.*

If the atmosphere consisted only of the mixture of gases known as air, conditions on this planet would be very different from what they now are. The characteristics of the air as we know it are largely determined by the very small proportion of solids and liquids which form vast, or merely large disperse systems, in it.

Of these disperse systems some are natural and of meteorological significance, whilst others which may or may not be of similar significance are the result of human activities, which they, in turn, may greatly affect. The former class are mainly systems in which water is the major constituent of the disperse phase, whilst the latter are more varied in character. The great dilution of most of these systems, together with the low density and viscosity of the medium, makes investigation difficult, and the systems themselves unstable. The most obvious visual means of investigation have given us classification of clouds, based on Luke Howard's nomenclature, an international scale of visibility and various more or less satisfactory methods of gauging smoke density for the purpose of administering very difficult Acts of Parliament.

## Ions and Nuclei.

The study of the conduction of electricity through gases has shown that charges are carried by (a) "small ions" which behave as if they were aggregates of up to 30 molecules (of something) carrying one electronic charge, and by (b) "large" or Langevin ions, similarly charged, but consisting of about a million molecules. The radius of small ions varies from about 3 to  $10 \times 10^{-8}$  cm. and of the Langevin ions from  $10^{-6}$  to  $10^{-5}$  cm., but there is no sharp division, it appears probable that large ions are Aitken nuclei (c) which have captured small ions and thereby become charged. Aitken nuclei, whether charged or uncharged, have a mean radius something under  $5 \times 10^{-6}$  cm.

J. J. Nolan and P. J. Nolan<sup>1</sup> have described a new method of counting small ions which, they claim, yields results with ease and accuracy. Large ions can be determined by differential counts with Aitken's counter, with and without a condenser to remove charged nuclei (ions). Scrase<sup>2</sup> has recently investigated the Aitken counter, in which the number of hygroscopic nuclei is determined by counting the drops falling on a graticule after the adiabatic expansion of a determined volume of air saturated with water vapour. Aitken<sup>3</sup> at first (1879) believed that the hygroscopic nuclei thus counted were dust particles, and continued to call them so after he had realised that they were droplets of unknown

<sup>2</sup> F. J. Scrase, *Quart. J. Roy. Met. Soc.*, 61, 367-79.

<sup>3</sup> J. Aitken, *Coll. Sci. Papers*, 1923, 34-74.

composition. On this point, M. G. Bennett<sup>4</sup> says "As to the source of the nuclei, there are two obvious possibilities—the sea and chimneys. No doubt the sea provides most of the nuclei operative in genuine sea fogs, and chimneys are able to provide all the nuclei required for town fogs; but the main source of such nuclei in country air is still a matter under discussion. . . ." N. Fuchs<sup>5</sup> also refers to the lack of knowledge of the nature of large ions:—"Die einzigen bisher untersuchten amikroskopischen Aerosole waren die sogenannten Langevinschen Ionen, d.h. geladene Teilchen von ganz unbestimmter Natur." There is undoubtedly much evidence supporting the view that many of the nuclei found in air everywhere are the result of the evaporation of droplets of sea water projected into it by breaking waves and whirled over the earth by the action of winds. I have repeatedly found chlorions in water condensed from London air and, although these may in part have resulted from the volatilisation of the chlorine often found in some form (not, apparently, invariably, as chlorides) in coal, the sea seems a more prolific source. Rain water, each drop of which had its origin in a nucleus, seems invariably to contain chlorions,<sup>6</sup> as does river water, even in upland and mountainous districts. The water of rivers fed by tropical rains,<sup>7</sup> which usually fall in larger drops than in temperate climates, contains a less concentration of chlorions than that of European rivers,<sup>8</sup> where small raindrops may be considered as more concentrated solutions. The chlorion content of the Thames<sup>9</sup> (before it is contaminated with sewage, which raises the chlorion concentration) is of the order to be expected from the composition of the rainfall and subsequent evaporation. Further, Köhler<sup>9</sup> has analysed the saline content of both clouds and rime (derivatives of nuclei) in the Arctic circle, and based a theory of condensation on the contents of chlorides.

An argument for this theory can be based on the better agreement of the chlorion contents of the rain collected in two deposit gauges a few yards apart at Kew Observatory, as compared with other solid constituents, but this does not necessarily mean that the halogen is derived solely from the sea, since it is probable that the chlorine content of fuel may account for great part of it. In some tentative experiments I have not so far been able to detect bromine, which constitutes about 0.5 per cent. of the halogen content of sea water, in the Kew deposits.

H. L. Wright and I<sup>10</sup> have investigated the artificial formation of nuclei by burning various fuels (e.g. pure alcohol) in an enclosed atmosphere freed from pre-existent nuclei and from sulphur dioxide and other acid gases, and by the electrical heating of metal (e.g. platinum) surfaces, and found that formation of nuclei occurred. Of the hypotheses which may be advanced in explanation, the only one which appears to cover all the facts is that droplets of nitrous acid are formed from constituents of the air under suitable conditions of temperature, since this was detected and many nuclei found in the atmosphere after the experiments; nitrous acid was also found in the condensates. Fuming sulphuric

acid and sea water were found to be active producers of nuclei when sprayed into air, whilst other liquids were relatively feeble producers of nuclei. G. B. Courtier and I<sup>11</sup> have also found sulphuric acid in the condensate from London air which had been freed from sulphur dioxide. We therefore believe that although sea water is the chief constituent of nuclei in nature, most of the nuclei produced in civilised countries by the fires, furnaces, etc., associated with human activity are droplets of nitrous acid, some sulphuric acid probably being formed also. The formation of sulphuric acid in air containing sulphur dioxide gas with nitrous acid, partly in the gaseous phase and partly in droplets seems inevitable, but a study of sulphuric acid dispersoids in air by N. Fuchs<sup>5</sup> shows that combination occurs easily between droplets, so that a limiting concentration is easily reached beyond which the aerosol becomes unstable, and deposition on surfaces (leading probably to corrosion if they are metallic) occurs. Whether this is the correct, or at least a partial explanation, is difficult to say, but the concentration of sulphuric acid is very small, of the order of 1 per cent. of that of sulphur dioxide, in air.

Further work with Wright\* has shown that nuclei in London air may contain the nitric and ammonium ions, as well as those already mentioned. In each case the ions identified were found in condensates from air freed from sulphur dioxide. The known properties of solutions show that any soluble and hygroscopic substance in moist air is likely to yield Aitken nuclei, although at lower tensions of water vapour some solutes will be more effective as drop-formers than others.

The concentration of nuclei in air varies very greatly, but the number per c.c. is generally much less in country air than in that of towns. The concentration over the sea is also usually low. A few figures from various sources will show this, Table I. :—

Wright<sup>12</sup> (Fig. 1) has found a small seasonal variation in the number of nuclei in the air at Kew, the minimum occurring in the summer

<sup>11</sup> J. H. Coste and G. B. Courtier, Paper No. 23.

\* *Unpublished.*

<sup>12</sup> H. L. Wright, *Quart. J. Roy. Met. Soc.*, 1935, 61, 71-80; and *Geophys. Mem.*, No. 57.

months June to August. He also found a distinct decrease as the day advanced from nine hours to fifteen hours. Mm. Thellier in Paris<sup>13</sup> also found nuclei "*beaucoup moins nombreuses l'après-midi que le matin*," but observed no marked seasonal variation.

Aitken<sup>14</sup> pointed out that what he called "purifying areas" existed "where most clouds are formed and most rain falls." In four of these areas he found in the years 1889 to 1893 the lowest number of "particles" in the air coming from

Mediterranean.	Alps.	Highlands (of Scotland).	Atlantic.
891	381	141	72
the averages for these localities being			
1611	892	552	338

Over the narrow English Channel (presumably between Calais and Dover) he found 7000, but Bennett states that "the numbers of large ions and Aitken nuclei at sea (about 200 per c.c.) are very much less than over land."

The mean mass of a nucleus is less than  $1 \times 10^{-15}$  gm. J. J. Nolan and V. H. Guerrini<sup>15</sup> have recently found that the radius of the nuclei in Dublin air is  $2.85 \times 10^{-6}$  cm. and their mass  $1.68 \times 10^{-16}$  gm. The mass of the nuclear content of the air, even when the number is up to  $10^6$ /c.c., is of the order of  $10^{-6}$  of the water content of saturated air.

FIG. 1.—Seasonal variation of dust particles and nuclei at Kew, 1928-30 (Wright).

**Fog and Cloud** are derivatives of nuclei, formed by condensation on them of water vapour. M. G. Bennett<sup>4</sup> gives the limits of radius of fog droplets as from  $4 \times 10^{-4}$  cm. to  $3 \times 10^{-3}$  cm., with velocity of falling from 0.2 to 11 cm./sec. and of cloud drops an upper limit of  $1 \times 10^{-2}$  with a velocity of falling of 121 cm./sec. remarking "it is seen that a small fog droplet falls so slowly that it may be regarded as almost permanently suspended, and even in the case of a large drop, a current

of air rising with quite a reasonable velocity would be sufficient to maintain it at a constant height."

When air contains, besides natural dispersoids, tarry or sooty particles, coalescence occurs to a greater or less extent and, since fog is usually associated with still air conditions, the concentration of smoky particles becomes very high and the fog assumes the yellow to black hue well known to dwellers in large towns. Since most fuel contains sulphur, the concentration of sulphur dioxide and to a less extent of sulphuric acid becomes high, and the fog is irritant as well as dark. The variation of sulphur dioxide and black suspensoids during the fog of 23rd December, 1935, in London, is shown for part of the day in Fig. 2. With a temperature inversion over and around a large city the combined

FIG. 2.—Owen's filter shade and SO<sub>2</sub> at County Hall, London, during foggy day, 23rd December, 1935.

result of this and the heating effect of many warmed buildings may cause an overhead fog with darkness but reasonable clarity in horizontal directions. Professor Firket will speak on the effect of such a sulphurous fog in the Meuse valley.

**Rain Drops** as the ultimate derivatives of nuclei, may reach a radius of about 0.27 cm. (approximately the maximum calculated from the surface tension of water against air), and fall through air with a terminal velocity of about 800 cm./sec. Even such a large drop must spend a considerable number of seconds in falling from a cloud to the surface of the earth, and smaller drops spend much longer. During its fall, a drop is likely to become associated with other dispersoids in the air, and Dr. F. J. W. Whipple and I have found\* that rain water collected

\* Unpublished.

in a clean vessel contains appreciable amounts of salts and of insoluble matters. Some portion of the salts is accounted for by the hygroscopic nuclei on which drops form, but insoluble matters can only be derived from suspensoids in the air. The fact that considerable amounts of soluble and insoluble solids are found in water collected in deposit gauges used for investigation of atmospheric impurity<sup>6</sup> can hardly be adduced as proof that rain itself actually contains other non-aqueous matter than is derived from nuclei, since some may have been washed from dust falling into the gauges in dry periods, but all the matter collected in these gauges is derived from dispersoids in the air, and it may amount during a month to kilogrammes per square dekametre.

The nature of this solid matter (some of which is undoubtedly proper to the nuclei) is investigated, in a limited way, under the scheme of the Atmospheric Pollution Committee, the deposits of soluble and insoluble matter being determined and separated into tar, carbonaceous matter other than tar, sulphates, chlorides and ammonia. I have found on microscopical examination of the insoluble matter collected in London deposit gauges: spheres of fused matter—some glassy with gaseous inclusions, some opaque and light coloured with a warty surface, as if bubbles of gas had reached the periphery and burst as the mass solidified, some of magnetic iron oxide, others of coke, sintered sausage-shaped particles also evidently formed at a high temperature, coal, charred wood, textile fibres, plant hairs and other vegetable tissues, sand mostly from quartz, less often from flint, and occasionally scales of lepidoptera.

**The Finer Solid Dispersoids of Air** can be determined with reasonable accuracy by dust counters of which the Owens jet instrument<sup>6</sup> and the thermal precipitation instrument designed by Whytlaw Gray and Green<sup>6</sup> are the most efficient, or by Owens' air filter,<sup>6</sup> which is applicable only for black (soot) particles, in which the stain on paper through which a known volume (usually 2 litres) of air has been filtered, is compared with the stain produced by a known mass of carbon. An interesting investigation was carried out by H. G. I. Robins in the country around Norwich, and the results were discussed by Professor David Brunt,<sup>16</sup> who found (*inter alia*) that "the pollution is greatest in winter, least in summer, and intermediate (and equal) in spring and autumn," and "reaches an approximately steady value, showing no further diminution, at a distance estimated at 4 miles in spring, 5 miles in summer and autumn and 6 to 7 miles in winter." Brunt also concluded "that the cloud is effectively 4 or 5 miles wide at 3 miles from the city. As it is at least 2 miles wide initially, this result is not surprising."

The quantity of dispersed matter collected on the cover glass of a dust counter or the paper of an air filter is too small for ordinary microchemical analysis, but I have *qualitatively* examined stains filtered on ashless paper from several cubic feet of air in the manner suggested by G. M. B. Dobson.

Calcium carbonate and sulphate were found, in addition to soot and tar, in stains obtained by Dobson at Oxford, and kindly placed at my disposal; no free acid was found by him when the stains were fresh, but the presence of calcium carbonate and sulphate accounts for this, as calcium carbonate is likely to be present in air in amount enough to neutralise any acid droplets which come in contact with it, and which are most probably present, though, as Courtier and I show in another paper, only in very small amount.

<sup>16</sup> D. Brunt, *The Invest. Atmo. Poll, 17th Report*, 50-58.

### Living Matters.

An interesting and important group of suspensoids found in air comprises living and dead organisms and organic structures. Bacteria, moulds (spores), spores of ferns, pollen grains and infusoria in the loricated state may fairly be considered as dispersoids, but it would hardly be legitimate to include seeds with pappi or winged animals.

Bacteria and moulds in air have been investigated by many workers, but the subject has received no systematic attention. My colleague, Dr. J. Graham Forbes, F.R.C.P., examined the bacterial and hyphomycete content of the air of the London tube railways,<sup>17</sup> and with the exception of one or two pathogenic species of *aspergillus* among the moulds, no definitely pathogenic organisms were identified out of the large number of colonies examined. W. F. Wells has studied air borne infection.<sup>18</sup>

Interesting proof of the distribution of fern spores in air can be seen in the growth of ferns in the neighbourhood of the electric light bulbs lighting the Cheddar caves and Kent's Cavern at Torquay. I found an interesting case of air-borne vegetable suspensoids at Arcachon. The streets were strewn, in places where dust could collect, with a bright yellow, sulphur-like powder; it was also on the sands of the seashore. Examined microscopically, it was indistinguishable from the pollen of *pinus maritima*, grown in the forests along the Basque coast for the production of turpentine. The appearance of growths of *protococcus viridis* and, rarely, of the red variety *hæmococcus* in any stagnant water, whether in a waterbottle or a roadside puddle, and on the bark of trees is evidence of its widespread occurrence in air, and of the readiness with which it will settle out under quiet conditions.

Hygroscopic nuclei and the finer dispersoids, sooty or otherwise, are found in greater quantity in town than in country air. This is only to be expected, since the higher numbers are always associated with fire, which is a relatively rare phenomenon in nature. An exception should, perhaps, be made of volcanic districts, but I have found no observations on this point, except the ascription of various phenomena to the dust projected into the air in the Krakatoa eruption. The few specimens of Krakatoa dust which I have seen were very coarse, and could not have remained in the air for long.

The relatively large vegetable suspensoids may mostly be derived from country sources, but few observations of atmospheric impurity have, it seems, been made on country air, compared with the large number on town air. I hope in the near future to be able to work on country air. It may, however, be remarked that the leaves of plants in towns are usually covered with dust (largely of the kind associated with chimneys), whilst leaves in the country (now that our roads are no longer dusty), are seldom obviously dusty.

**Characteristic Town Suspensoids**, above the dimensions of nuclei and soot or dust-counter particles (from, say, 1 to 1000  $\mu$ ) mostly result from combustion of solid fuel, and consist of silicates (if from industrial furnaces usually spheres, showing complete fusion of the fuel ash, or sintered particles) with particles having the characteristic foam structure of coke and sometimes covered with minute spheres of ash.\* Ash from

<sup>17</sup> J. Graham Forbes, *J. Hyg.*, 1924, 22.

<sup>18</sup> W. F. Wells, *et al.*, *Amer. J. Hyg.*, 1934, 20, 611-18; *ibid.*, 619-27.

\* If combustion had gone on further, they would either have coalesced or become free spheres; domestic fires, on the other hand, where the temperature is lower, yield a flaky or shaly ash.

pulverised fuel furnaces, usually consists of spheres which are often hollow, or at least contain gas inclusions, although long sintered particles are sometimes seen. This hollow form causes them to have a lower apparent density than would be expected of silicates,<sup>20</sup> but grinding in an agate mortar will bring up the density and show "postage stamp fractures" where bubbles of gas have been broken. It is rather remarkable that pulverised fuel ash often contains a very appreciable proportion of unburnt coke. Another characteristic constituent of ash from high temperature furnaces is magnetic oxide of iron in spheres or sintered fragments; they contain ferrous and ferric iron, and are readily magnetised. That this has been fused indicates a temperature of about 1600° C.

Some notion of the nature of the coarser dispersoids falling through the air can be gathered from examination of the insoluble matter collected in the standard deposit gauges. Those in the London parks collect spheres, indicating industrial pollution, with coke and amorphous or laminar "ash," probably from domestic grates, some coal and charred wood from the same source, textile fibres, with vegetable hairs and tissues of horticultural origin. The Kew deposits are more definitely horticultural and domestic, with small spheres, few in number, due to industry. A'l contain quartz sand. Leaves from a marsh around a power station burning pulverised fuel showed lodgements of spheres along the midrib, some of magnetic oxide, whilst leaves from Teddington Railway Station were covered with ferric oxide with some spheres; the ferric oxide I attribute to the erosion and corrosion of the live rails of the electrified system; few steam trains pass through this station. Dust collected from leaves and from a raised wooden platform in my garden at Teddington, contained much sand, and some coal and coke, with very few spheres. Dust from leaves in Battersea Park, near the Power Station, was mostly domestic and horticultural in origin, very few spheres being found, showing the efficiency of the gas washing plant. Ivy leaves from sheltered places around the village of Cockington, near Torquay, yielded a fine, reddish sand, with calcium carbonate, chlorides and traces of sulphates, vegetable hairs and tissues, unicellular green algæ and mycelia, but no obvious ash, coke, coal or soot.

The chemical and microscopical analyses (Table II.) of grit (a) from the roof of a London railway terminus, taken during a cleaning; (b) from the

## Summary.

The dispersoids found in the air are partly normal to it. These have water for their main constituent. Others which are natural in origin, but are associated with air which has travelled over land, are living cells. The air of towns, or which has travelled over towns, contains droplets formed from the gaseous products of combustion, and tar, soot and ash from the combustion of fuel. Fine silicious matter may be found in the air of town or country. The concentrations of these dispersoids, even in highly polluted air, are very low.

## GENERAL DISCUSSION.\*

**Mr. C. F. Goodeve** (*London*): asked what was meant by the "unstable size" referred to. The discussion of the equilibrium conditions obtaining in droplets, given both by Köhler and by Dooley and the speaker in papers to this discussion, indicates the existence of no such unstable size with the properties described by Dobson.

**Professor F. G. Donnan** (*London*) said he thought that modern workers would do well to study the classical work of Willard Gibbs on the thermodynamics of "surfaces of discontinuity." It was extraordinary how little people knew about the profound investigations of Gibbs on the formation and stability of films and liquid drops.

**Professor H. Köhler** (*Uppsala*), in introducing his paper, added:

(1) The latent heat of condensation,  $\lambda$ , mentioned on page 1157, is derived as follows:—

The energy equation requires

$$q = dU + A p dv \quad . \quad . \quad . \quad (1)$$

where  $U$  is the internal energy of the system and  $A p dv$  the work in heat-units performed by the system. We now bring in  $T$  and  $x$  as independent variables:

$$dU = \frac{\partial U}{\partial x} dx + \frac{\partial U}{\partial T} dT \quad \text{and} \quad dv = \frac{\partial v}{\partial x} dx + \frac{\partial v}{\partial T} dT.$$

Dividing (1) by  $T$ , we obtain the change of entropy  $dE$ .

$$dE = \frac{q}{T} = \left( \frac{\partial U}{\partial T} + A p \frac{\partial v}{\partial T} \right) \frac{dT}{T} + \left( \frac{\partial U}{\partial x} + A p \frac{\partial v}{\partial x} \right) \frac{dx}{T}. \quad (2)$$

Since  $dE$  is a whole differential, we get:—

$$q = C dT + AT \left( \frac{\partial p}{\partial T} \cdot \frac{\partial v}{\partial x} - \frac{\partial p}{\partial x} \frac{\partial v}{\partial T} \right) dx. \quad (3)$$

In (3) the latent heat of condensation is:—

$$\lambda = AT \left( \frac{\partial p}{\partial T} \cdot \frac{\partial v}{\partial x} - \frac{\partial p}{\partial x} \frac{\partial v}{\partial T} \right).$$

If, now, we insert the tension and the specific volume of the drops and the vapour, we get:—

$$\lambda = \lambda_0 + \frac{2AT\psi'}{r} \frac{\partial}{\partial T} \left( \frac{s}{T} \right) - AR_1 T \times \frac{\partial \log e}{\partial x}.$$

The latent heat of condensation on droplets of a solution,  $\lambda$ , is derived without assuming any change of the entropy, but from the energy equation and from the fact that  $dE$  is a whole differential.

(2) The number,  $N$ , of droplets mentioned in my paper is the same as the number of nuclei accompanying the rising air, and the system is cooled

\* On the three preceding papers.

adiabatically. On this assumption, the process is reversible. One must remember that change of entropy is entirely determined by the initial and terminal values. I have not examined isothermal processes.

(3) According to theory, a relation should exist between the concentration and the number  $N$ . This I have never found experimentally. I therefore conclude that the growth of droplets must take place otherwise; if coalescence take place (or evaporation from some droplets and simultaneous condensation on others) the process is irreversible.

**Mr. C. F. Goodeve** (*London*): Asked why Köhler applied thermodynamical equilibrium considerations to his droplets but denied that equilibrium obtained during the condensation of the fog to form hoar frost. *Microscopic* investigations could not *prove* that the hoar frost had the same composition as the fog from which it was deposited, and experiments in other cases have shown that equilibrium conditions are very rapidly set up. The speaker considered it essential to prove this point before consideration could be given to the extensive data obtained by Köhler.

The whole-number rules were very interesting, and further experiments showed intermediate series. How was it possible to reconcile this whole-number rule with the thermodynamical considerations given later in the paper?

The conclusion with regard to the latent heat of evaporation in the unstable region (where the slope was negative), Fig. 1, is of doubtful validity. Droplets in this region are very unstable, as is pointed out in a later paper by Dooley and Goodeve. It is not useful to apply entropy considerations to a system which is essentially irreversible.

**Mr. J. H. Coste** (*Teddington*) said: The chlorion content of rainwater has been determined in many places. I think Professor Köhler would find much information in Clarke's *Data of Geochemistry*. The water of large rivers in tropical districts, and of upland streams, is of the order given by Professor Köhler for rainwater, which would be expected. I find, on looking at the analyses published by the Atmospheric Pollution Research Committee that there is a tendency for the chlorion content of rainwater in towns to be higher in winter than in summer. How far this is due to salt brought in by wind from the sea, or alternatively to chlorine from coal is difficult to say, but the halide content of fuel is by no means negligible.

**Professor F. G. Donnan** (*London*) said that some eminent landscape painters had drawn his attention to the haze which always existed in England with an East wind. He could confirm these observations from his own experience. His artist friends found it impossible to paint when the East wind (fine weather) haze blotted out all detail. As soon as the wind changed to the South or West, this particular haze disappeared. Was it due to Continental or other dust nuclei which remained in suspension in the relatively dry air-currents of the East wind, and which were rapidly deposited by adsorption or absorption of water from the moist, southerly and westerly air-currents?

This peculiar and very intense haze was quite different from ordinary mists or fogs, or from the well-known "sea frets" which sometimes invaded the land areas.

**Dr. F. T. Peirce** (*Manchester*) said: Would the landscape painter distinguish between light scattering by particles and refraction by convection currents, which may be more pronounced in East wind weather when the upper air is cold and the ground warmed by bright sunshine?

**Dr. R. Meldau** (*Berlin*) said: Almost a hundred years ago, Chr. G. Ehrenberg described "the abundant invisible air-borne organic life" which he had studied, described and pictured over a period of many decades.<sup>1</sup> Svante Arrhenius developed along similar lines the hypothesis of the

<sup>1</sup> *Abhand. Königl. Akad. Wiss., Berlin, 1871 et seq.*

*Panspermie* (*Allbesamung*). It might perhaps be useful to review the old work of Ehrenberg in the light of modern knowledge.

Dr. W. H. J. Vernon (*Teddington*) (*communicated*): An indication of the nature of dispersoids in country and town air is afforded by the wind-borne constituents of certain metallic corrosion products, *e.g.* the familiar green patina on copper.<sup>2</sup>

ANALYSIS OF WIND-BORNE MATERIALS IN THE GREEN PATINA ON COPPER FROM TYPICAL SOURCES.

	N. Mims Spire, Hert- fordshire.	Bodleian Library Roof, Oxford.	British Museum Dome, London.	Customs House Dome, Ramsgate.
Per cent. wind-borne matter in green patina . . .	9.6	6.9	19.2	4.3
<i>Per Cent. Constituents in Wind-borne Matter.</i>				
Iron oxides (as $\text{Fe}_2\text{O}_3$ ) . . .	43.0	64.3	24.2	36.6
Alumina, $\text{Al}_2\text{O}_3$ . . .	47.4	13.4	37.0	17.0
Carbonaceous matter . . .	6.4	11.9	32.6	9.7
Siliceous matter . . .	3.2	10.4	6.2	36.6

The high proportion of iron oxide and alumina is striking, although it is difficult to deduce any topographical relationship; well-marked maxima are exhibited by carbonaceous matter in the town sample, and by siliceous matter in the marine sample.

The nature of the dispersoids has also a great influence in determining the composition of the main part of the product, *i.e.* the part derived from corrosion of the underlying metal. The characteristic constituent in country atmospheres (in Great Britain) is basic copper sulphate, derived mainly, no doubt, from the action of sulphur dioxide either in gaseous or dispersoid form, although ammonium sulphate particles must play a subsidiary part.<sup>3</sup> In town atmospheres the proportion of basic copper carbonate is very greatly increased, rising to nearly 25 per cent., compared with 2.7 per cent. in rural atmospheres, due in part at least, to a higher proportion of carboxylic acids in town air,<sup>4</sup> almost certainly in dispersoid form; but, as suggested by Mr. Coste,<sup>5</sup> this factor is probably supplemented by the greater amount of calcium carbonate diffused into town air, from mortar, cement, limestone, etc.

Although particles of chlorides derived from the sea provide effective nuclei for rain drops at much greater distances, they cease to be effective from the corrosion point of view at comparatively short distances from the sea, unless they are favoured by prevailing winds. Thus, at inland sites in this country chlorides are absent from the copper patina. In samples taken in mid-Wales, 30 miles from the sea, there is 20.75 per cent., and at Dundalk, on the north-east coast of Ireland, only 8.1 per cent. basic copper chloride. The occurrence of the greater chloride at the greater distance from the sea is here clearly attributable to the influence of prevailing winds.

It seems right to emphasise the undoubted importance of dispersoids in atmospheric corrosion phenomena, especially as this aspect has not been formally represented elsewhere in the discussion. The fundamental part

played in the corrosion of iron by suspended particles (sufficiently small to have Brownian movement and capable of interception by a simple muslin screen) was demonstrated by the writer some years ago,<sup>6</sup> and its importance has been amply confirmed in more recent experiments.<sup>7</sup>

**Professor H. Köhler** (*Uppsala*), in reply, said: Without doubt there are different kinds of hygroscopic nuclei in the atmosphere. According to my calculations, the larger nuclei of a definite kind must first be considered, and then smaller and smaller: the mass is decisive. If different kinds of nuclei are present, however, the mass is not of paramount importance, but their respective hygroscopic powers also come into consideration. In large towns and industrial countries the atmosphere gains many very hygroscopic nuclei, are emitted into the atmosphere, and these have the same effect as the less hygroscopic seasalt.

My results on condensation and the constitution of clouds, appear to conflict with thermodynamics, which has not been uncommon in meteorology since Hertz 1884. If we assume that condensation on adiabatic expansion of the air takes place on nuclei which are present, results are obtained which do not correspond with reality. Droplets cannot grow by continuous condensation to the size of raindrops, or even to that of cloud droplets.

The latent heat of condensation is deduced for condensation on droplets consisting of pure water.<sup>8</sup>

The vapour tension of the droplets of solutions for the condition  $\alpha^2 < \alpha_1^2 \cdot 2^{-12}$  decreases or to some extent is almost constant on adiabatic cooling, it is also a function of  $T$ . Smaller seasalt-nuclei than  $\alpha_1^2 \cdot 2^{-12}$  are not available for the condensation in the atmosphere, because too great supersaturation then would be necessary. It is also important when considering equilibrium conditions to define accurately the vapour tension of a droplet present in the atmosphere, with regard to the measured mean value of the pressure of the water vapour.

The constitution of the hoar-frost deposited from fog, has been examined in other than microscopic ways and the same results were always obtained.<sup>9</sup>

**Mr. J. H. Coste** (*Teddington*), in reply, said: Sir Robert Robertson had informed him in correspondence of the work on products of combustion to which he referred at the meeting. It was interesting to receive this confirmation of the frequent presence of nitrous acid in air contaminated with smoke from chimneys. Dr. Vernon's figures seemed to show that wind-borne matters, and especially silicates and carbon were more prevalent in town air.

As to the products of corrosion of copper he was inclined to think that the basic copper sulphate was a residual product, since he had found crystals of normal copper sulphate, on copper surfaces exposed to the air and dew, but not to the leaching effect of rain.

He was very interested in what Dr. Meldau had to say about Ehrenberg, whose microscopical work was well known, with whose researches on atmospheric dispersoids he was not acquainted. The early microscopist, Leowenhoeck, had made some evidently very careful examination of the dispersoids in rainwater, and Angus Smith had done a great deal. He would seek the opportunity of reading Ehrenberg's papers.

# THE DETERMINATION OF THE MASS AND SIZE OF ATMOSPHERIC CONDENSATION NUCLEI.

BY J. J. NOLAN AND V. H. GUERRINI.

*Received 6th February, 1936.*

In 1903 J. J. Thomson<sup>1</sup> and Langevin<sup>2</sup> independently demonstrated the possibility of the existence in a non-saturated atmosphere of stable drops of water of diameter of the order  $10^{-6}$  cm. In 1905 the large atmospheric ions were discovered by Langevin and were found to be of a certain degree of homogeneity as regards their mobility. It was natural, then, to assume that the large ions were the condensation nuclei, familiar owing to the work of Aitken, which had acquired positive and negative charges, and that the condensation nuclei were the stable uniformly-sized drops, the theoretical possibility of which had been indicated. Whatever be the nature of the condensation nuclei, the identification of the large ions with the charged nuclei may be said to have been firmly established by all later work.

In 1917, J. J. Nolan showed<sup>3</sup> that, assuming the large ions to be spheres of water, calculations of their size made by a kinetic-theory formula due to J. J. Thomson and by Millikan's modification of the Stokes-Cunningham formula were in good agreement. For ions of mobility 0.00033 cm./sec. in a field of 1 volt/cm., assumed to carry unit electronic charge, the radius calculated was  $4.1 \times 10^{-6}$  cm. The fact that the charge on the large atmospheric ion is normally the electronic charge was afterwards demonstrated.<sup>4</sup> More recently, J. J. Thomson and G. P. Thomson,<sup>5</sup> from calculations somewhat similar to those already referred to, obtained the value  $4.5 \times 10^{-6}$  cm. An interesting calculation of a different kind might be mentioned. By attributing the absorption of solar radiation to the condensation nuclei, P. J. MacLaughlin<sup>6</sup> from experiments made at the top and bottom of the Eiffel Tower, calculated a value  $5.5 \times 10^{-6}$  cm. for the radius of the nuclei.

The possibility of making more precise measurements of the nuclei was disclosed as a result of some observations<sup>7</sup> directed in the first instance towards the investigation of the manner in which nuclei are lost from an air-stream flowing through tubing. It appeared that the loss of nuclei could in general be attributed to two effects, gravity and diffusion to the walls. It was possible also in general to separate these effects, to estimate the amount of each separately, and hence to deduce the terminal velocity of fall of the nuclei and their diffusion coefficient in air.

### Experimental Methods.

In order that the losses of nuclei should be sufficient to enable accurate observations to be made, it is necessary that the air carrying the nuclei should pass very slowly through a rather narrow channel. The most convenient way to secure this is to cause the air to flow in a thin sheet between parallel plates. By building up a pile of plates with suitable separators, several such air-sheets may be arranged to flow in parallel. When the planes of the plates are horizontal, the loss of nuclei is due both to diffusion and fall. When the plates are set with their planes vertical, the loss by fall is negligible and diffusion alone may be held to operate.

In our experiments a water-sealed gasometer of capacity about 500 litres was filled with a mixture of filtered air and atmospheric air containing the nuclei under examination. The air in the gasometer, having a concentration of about 5000 nuclei per  $\text{cm}^3$  was driven, under a suitable head of pressure through the parallel-plate system. At the inlet and outlet of the system, the number of nuclei per  $\text{cm}^3$  of air was counted by an Aitken apparatus. Each determination of velocity of fall and of diffusion coefficient involved a large number of readings of the Aitken instrument at each end of the apparatus under the two conditions of plates horizontal and plates vertical.

### Calculation of $V_g$ , the Velocity of Fall.

If we assume a uniform concentration of nuclei in the air entering the apparatus and conditions of stream-line flow in the space between the

FIG. 1.

plates, it is easily shown that the fraction  $k$  of nuclei lost is connected with the terminal velocity  $V_g$  by the relation

$$V_g = \frac{6Q}{Lb} \left( \frac{k^2}{2} - \frac{k^3}{3} \right),$$

where  $Q$  is the volume of air passing per second between the plates,  $L$  is the horizontal length and  $b$  the breadth of the space.

Since the quantity  $k$  (fraction of nuclei lost by fall) is obtained as the difference between the fractions lost in the horizontal and vertical positions of the plates, it is in general small, and is not readily determined to a high degree of accuracy.

The amount of agreement between the experimental and the theoretical loss by fall obtainable under favourable conditions may be judged from Fig. 1, in which values of  $k$  obtained with various values of the air-stream are plotted. The continuous curve shows the theoretical relation between the quantities for an assumed velocity of fall of  $8 \times 10^{-5}$  cm./sec.

### Calculation of $D$ , the Coefficient of Diffusion.

It has been shown<sup>7</sup> that the loss of particles by diffusion from air flowing through a thin rectangular channel may be expressed in the form

$$\frac{n}{n_0} = 1.066 \exp. \frac{-3.67bDz}{aQ} + 0.0065 \exp. \frac{-44.4bDz}{aQ},$$

where  $n/n_0$  is the ratio of the concentrations of the particles in the air entering and leaving,  $b$  is the breadth,  $z$  the length and  $a$  the half-depth of the channel and  $Q$  is the volume of air passing through per second. Since the second term will, in practice, always be negligibly small, the relation can be expressed as

$$n/n_0 = 1.066 \exp. -x, \text{ where } x = 3.67 bDz/aQ.$$

From the nature of the observations, it is to be expected that the determinations of  $D$ , the diffusion coefficient will be of a higher order of accuracy than those of  $V_0$ . The values found do, in fact, exhibit a higher degree of consistency. Fig. 2 shows values of  $n/n_0$ , obtained

FIG. 2.

under conditions not specially favourable, plotted against  $Q$ , the volume of air passing per second. The continuous line shows the theoretical relation between the quantities for an assumed value  $D = 18 \times 10^{-6}$  cm.<sup>2</sup>/sec.

It appears generally from our observations that the loss of nuclei can be completely accounted for by the two processes of fall and diffusion, and that the processes can be separately observed. In our experiments three sets of apparatus differing widely in dimensions were used. The particulars of the materials and dimensions of these are set out in the following table:—

Appa- ratus.	Material of Plates.	Thickness of Plates.	Length.	Breadth.	Depth.	Number of Channels.
I	Glass	0.211 cm.	76 cm.	19.0 cm.	0.211 cm.	7
II	Duralumin	0.046 "	100 "	24.9 "	0.642 "	7
III	Brass	0.054 "	30 "	9.9 "	0.054 "	10

The results of observations made on nuclei in Dublin air are collected in the following table. It should be stated that the air was not drawn

directly from the open. It was room air, not contaminated in any way, but differing from atmospheric air in that the nuclei in it were older on the average than those in the outside air.

Apparatus.	$V_g \times 10^6$ , cm./sec.	$D \times 10^6$ , cm. <sup>2</sup> /sec.	The values set out in this table are means derived from figures which, especially in the case of $V_g$ , show very considerable scatter. This variation in the values found may be regarded as due in part to the inherent experimental difficulties, and in part to the fact that the observations were spread over many months, with very varied weather conditions, and possibly considerable real variation in the character of the nuclei. It is satisfactory that the mean values found with the different apparatus are in fair agreement. We may conclude with a certain measure of assurance that the values $V_g$ and $D$ for the nuclei we have been observing are close to
I. 1st Series	8.6	17.5	
2nd "	6.9	18.1	
II.	8.2	20.9	
III.	7.2	17.4	

the inherent experimental difficulties, and in part to the fact that the observations were spread over many months, with very varied weather conditions, and possibly considerable real variation in the character of the nuclei. It is satisfactory that the mean values found with the different apparatus are in fair agreement. We may conclude with a certain measure of assurance that the values  $V_g$  and  $D$  for the nuclei we have been observing are close to

$$\begin{aligned} V_g &= 7.5 \times 10^{-5} \text{ cm./sec.} \\ D &= 18 \times 10^{-6} \text{ cm.}^2/\text{sec.} \end{aligned}$$

and

### Calculation of Mass and Size.

The well-known Einstein equation gives the mobility, *i.e.* the ratio of the velocity of a particle through a gas to the force acting on it  $= DN/RT$  we have therefore

$$\frac{V_g}{mg} = \frac{DN}{RT} \quad \text{and} \quad m = \frac{V_g}{D} \cdot \frac{RT}{ng}.$$

The mass of the nuclei observed in our experiments is therefore

$$\begin{aligned} m &= \frac{7.5 \times 10^{-5}}{18 \times 10^{-6}} \cdot \frac{831 \times 10^5 \times 288}{6.06 \times 10^{23} \times 980} \\ &= 1.68 \times 10^{-16} \text{ g.} \end{aligned}$$

If we assume that the nuclei are spherical we can write the Einstein equation in the form

$$D = \frac{RT}{N} \cdot \frac{1 + l/a (A + B \exp. - ca/l)}{6\pi\eta a}.$$

Knowing the constants in this equation, we can use it to calculate  $a$  for different values of  $D$ . Values of  $A$ ,  $B$  and  $c$  have been given by Millikan<sup>8</sup> and Mattauch.<sup>9</sup> While these values differ, they give, over the range with which we are concerned, curves of  $D$  against  $a$  which are practically identical. From these curves we find for  $D = 18 \times 10^{-6}$ ,  $a = 2.85 \times 10^{-6}$  cm. The volume of such a particle will be  $0.97 \times 10^{-16}$  cm.<sup>3</sup>. Comparing this with the value  $1.68 \times 10^{-16}$  gr. found for the mass, we arrive at  $1.68/0.97 = 1.7$  for the density of the nuclei.

### Effect of Time.

The values for mass and radius which we have just given are calculated from the results of a great many experiments, all made on room air, and refer therefore to nuclei to some extent aged. During the

<sup>8</sup> R. A. Millikan, *Physic. Rev.*, 1923, **22**, 1.

<sup>9</sup> J. Mattauch, *Z. Physik.*, 1925, **32**, 439.

duration (about two hours) of each experiment, the nuclei were contained in a water-sealed gasometer. There was no indication that, during the time of the experiment, any change in the nuclei occurred. On long standing however the evidences for change are quite definite. There is a reduction in the values of both  $V_0$  and  $D$ . If  $V_0$  and  $D$  fell off at the same rate, i.e. so as to keep  $V_0/D$  constant, it would mean that the nuclei were increasing in size, but that their mass was remaining constant. Our observations made so far tend to show that  $V_0$  diminishes more rapidly than  $D$ , so that it would appear that the nuclei surviving after a certain lapse of time are (1) larger, (2) of smaller mass, and therefore (3) of considerably lower density than the average at the beginning. It may be noted that P. J. Nolan<sup>10</sup> found that nuclei stored in the same way showed an increase with time in their coefficient of combination with small ions. These results are consistent with the supposition that the nuclei present originally are a mixture of different kinds, and that those observed after a lapse of time are the larger and lighter ones which have escaped loss by diffusion and fall.

### Observations on Nuclei in Country Air.

We have made a number of observations on nuclei in the air at Glencree in the Wicklow Mountains, eleven miles south of Dublin. Here the concentration of nuclei varies over a wide range, large numbers being found when the air-supply comes from the direction of Dublin, while small numbers are usually found when the wind comes from the open country to the south and west. The results found so far indicate the possibility of a considerable range of variation in the sizes and masses of the nuclei. Observations are being continued with the object of determining the effect of the size of the nuclei on the control which they influence on the equilibrium of atmospheric small ions.

<sup>10</sup> P. J. Nolan, *Proc. Roy. Irish Acad.*, 1929, 38, 49.

### GENERAL DISCUSSION.

**Professor F. G. Donnan** (*London*) said he thought that the work of Professor Nolan and Dr. Guerrini represented a very important contribution to the problem of the nature of atmospheric condensation nuclei.

**Dr. G. M. B. Dobson** (*Oxford*) said: The minute particles seen in the normal atmosphere by the aid of the ultra-microscope appear to be of various sizes. Indeed, it would be very surprising if they were all closely the same size, as assumed by Professor Nolan in his calculations. In his observations with the plates of the instrument horizontal the particles which settle out will be chiefly the larger ones, while with the plates vertical the smaller particles will diffuse to the sides most rapidly. Thus, if the particles present have a large range of size his equations will not hold strictly.

I should like to suggest to Professor Nolan that he should make calculations to see what would be the effect on the results obtained if there were really present particles of many sizes. Thus, it would be interesting to know how the size he would obtain by the present method would differ from the true average size of the particles present.

**Professor R. Whytlaw-Gray** (*Leeds*) said: The distinction usually made between atmospheric nuclei and finely dispersed solid matter appears to me to be an artificial one. It is supposed that the former, on account of their hygroscopic character, condense moisture readily and form minute droplets, whilst the latter do not behave in this way at all, or do so only

with difficulty. For this reason the Aitken counter is supposed to innumerate the hygroscopic nuclei only, and the Owens' dust counter and the thermal precipitator the larger particles of solid material which are of microscopic dimensions.

Experiments made here with the Aitken instrument indicate that solid particles of such materials as silica, magnesium oxide, finely divided carbon, etc., readily act as condensation nuclei and can be counted and it seems probable that this method reveals not the hygroscopic nuclei only but the total number of particles of all kinds that are present.

Again, the view is often expressed that nuclei are of amicroscopic dimensions and hence are invisible in the ultramicroscope. Some of them no doubt fall into this category, but many nuclei and large ions can be seen and counted with the latter instrument. Support for these views is afforded by a comparison recently made in this laboratory of the Aitken counter with the ultramicroscope on a number of smokes and dusts. With smokes of stearic acid, carbon black, and paraffin, as well as with silica dusts, a close agreement was found. With ordinary Leeds air containing the usual amount of suspended pollution, the Aitken instrument counted about 30 per cent. more particles but when the air was enclosed in a large tank and comparisons made at intervals over a long period, the numbers counted became closer with lapse of time and at the end of three hours were approximately equal by the two methods.

These experiments appear to show that particles of various kinds and of a considerable size range are present in town air. Of these a certain proportion are amicroscopic and a much smaller proportion of microscopic dimensions. The most numerous are those which are usually classed as ultramicroscopic and fall approximately between the size limits of  $5 \times 10^4$  and  $2 \times 10^{-8}$  cms. radius, i.e., between  $0.05$  and  $0.2\mu$ .

The total number of particles observed in Leeds air when these experiments were made, was of the order of  $10^5$  per c.c. Those visible microscopically in the thermal precipitator records numbered about 3000 per c.c.

**Professor F. A. Paneth** (*London*) said: On the question whether particles of different size are to be found in air, I should like to know the opinion of meteorologists concerning the presence of particles too small to be seen even under the ultra-microscope. So far as I am aware, such particles have been postulated only by chemists, as a means of explaining variations in the density of air found in 1893 by Lord Rayleigh and more recently (1917) confirmed by Ph. A. Guye in Geneva; according to Guye, the weight of 1 litre of air can vary by several tenths of a milligram. If due to a difference in composition, this would correspond to a change in the oxygen percentage of more than 0.1 per cent. by volume which, of course, could readily be detected chemically; it is impossible to ascribe the density variations to any other alteration of the chemical composition of air. They seem to be connected with changes in the barometric pressure, and Guye suggests that the assumption of extremely fine particles of dust may provide an explanation. This, of course, is an *ad hoc* hypothesis made only after the failure of all other attempted explanations, and I wonder whether any meteorological observation can be quoted in its support.

**Professor R. Whytlaw-Gray** (*Leeds*) said, in reply: It is difficult to imagine any kind of fine particulate system present in air which would alter the density by as much as a few tenths of a milligram per litre, i.e., by a few parts in 10,000; the variation reported by Guye in the experiments quoted. In a fine smoke containing about  $10^4$  particles per c.c. an average value for the mass concentration is of the order of 20 milligrams per cubic metre. This could only alter the density by 1 part in 70,000, though its presence would be evident in the Tyndall beam. If the air were optically empty the particles would have to be about ten times smaller and even this small variation in weight would require a number concentration of  $10^8$  per c.c. which seems very unlikely.

**Mr. G. W. Slack** (*Leeds*) said: A variation of only one-tenth of a milligram corresponds to a mass concentration of one hundred milligrams per cubic metre and whilst a cloud of this concentration could no doubt be prepared which would give no sign of its presence in the Tyndall beam or ultramicroscope there can be little doubt that it would aggregate sufficiently to do this in a very short time, and so it is unlikely that this is the explanation of the observed variations.

**Mr. A. G. Grant** (*Darlington*) said: Has any attempt been made to define the properties of a nucleus? Previous papers have referred to hygroscopic nuclei, for example, sea-salt, and it has often been suggested that organic spores and particles of free carbon (in industrial fogs) may form nuclei. Professor Nolan's paper deals with molecular aggregates which are presumably somewhat bigger than Langevin ions. Are these aggregates credited with condensation properties resembling the hygroscopicity of sea-salt, or is there some more basic attribute which determines whether or not the smallest aggregates of matter may serve as nuclei?

**Mr. J. H. Coste** (*Teddington*) said: There seems no reason, in the nature of things, why hygroscopic nuclei should, in the air of inhabited districts, be all of the same kind or size. Wright and I have found various ions (in the chemical sense) in the condensates from London air, with some evidence of selective condensation. Professor Nolan has said that the density of 1.7 of the nuclei is not a figure on which much reliance can be placed, although it is of the right order. It would correspond to very strong solutions of any likely salt or hydride, and seems to be too high.

**Mr. C. H. Bosanquet** (*Billingham*) said: Are the diffusion and fall effects additive? It appears probable that the increase of particles striking the lower plate would be almost compensated by the decrease on the upper plate, if the velocity of fall is small. If this is the case, erroneous values of  $V_c$  would be obtained by applying the formula for  $k$  given in the paper directly to the values of  $k$  obtained by difference.

**Dr. J. J. Nolan** (*Dublin*), in reply, said: We have not been concerned in this work very directly with the nature of the condensation nuclei, but rather with an essay at the determination of the sizes of the bodies—whatever they may be—which are counted by the Aitken instrument. We have hitherto accepted the sharp distinction, apparently established by the work of Wigand and Boylan, between the condensation nuclei and the true dust. The question, however, is obviously an open one, and we await Professor Whytlaw-Gray's further results with great interest.

In the course of correspondence, it has been pointed out to us by Mr. Bosanquet that in the calculation<sup>7</sup> of  $V_c$ , while we have allowed for the difference in air-velocity in different levels of the air-stream, we have not taken account of the same difference as affecting the velocity of entry of particles into the apparatus. This consideration gives a simpler expression for  $V_c$ , and as a result of the correction (while a greater degree of coherence appears among the values calculated for different air-velocities), the results for velocities of fall are approximately doubled.

From experiments now in progress on atmospheric air contained in oil-sealed gas-holders, we hope to obtain a truer idea of the distribution of sizes of nuclei in the free atmosphere.

# HYGROSCOPIC NUCLEI IN THE FORMATION OF FOG.

BY JAMES C. PHILIP.

*Received 9th March, 1936.*

The fogs which have been the subject of investigation by the author and his collaborators<sup>1</sup> are those obtained on passing an air stream charged with a volatile acid through a solution of alkali hydroxide containing a trace of volatile alkali. When, for example, filtered air is drawn through concentrated hydrochloric acid and then through a solution of sodium hydroxide to which a trace of ammonium chloride has been added, a fog is produced in the alkali vessel, and this fog, once formed, is extraordinarily persistent. It can be passed through water without more than partial absorption and although passage through strong sulphuric acid appears to clear up the air stream, the fog reappears on subsequent bubbling through water.

The fog droplets can be removed from the air stream by woolly asbestos and submitted to analytical examination. This shows them to contain ammonium chloride and free hydrochloric acid and the weight of fog, obtained in a standard run, has been found to vary in a significant manner with the concentration of the alkali solution and with the amount of ammonia which it contains. The formation of fog can be detected even when the proportion of ammonia in the alkali solution is as low as 1 part in 10 million. Indeed, the production or non-production of fog under the conditions stated, provides as delicate a test for the presence of ammonia as the well-known Nessler reagent.

Our view of this phenomenon is that as the bubble of the air-HCl stream forms on the end of the inlet tube in the alkali solution molecules of ammonia from the latter combine with molecules of hydrogen chloride in the bubble producing nuclei of ammonium chloride; water then condenses on these hygroscopic nuclei, and the droplets so formed absorb free hydrogen chloride. On the bubble rising to the surface the suspended droplets escape into the vapour space above the solution, thus giving rise to the fog.

The point with which this communication is more particularly concerned is the question of the mechanism of formation of the droplets. Light is thrown on this matter by studying the manner in which the weight of fog and its composition are affected, under otherwise steady conditions, by changes in the vapour pressure of the alkali solution. As this vapour pressure is reduced it will be increasingly difficult for the nuclei to acquire water, and the weight of the fog droplets obtained in a standard run will decrease. Such a result has been obtained with sodium hydroxide solutions of greater strength than 1·0*N* concentration, but the most interesting evidence was provided by a series of experiments in which the vapour pressure of the alkali solution was reduced by the addition of sodium chloride.

<sup>1</sup> Askew, *J. Chem. Soc.*, 1927, 966; Aldis and Philip, *ibid.*, 1930, 1103; Jackson and Philip, *ibid.*, 1934, 341.

The data recorded in Table I. were obtained in a series of experiments<sup>2</sup> all carried out with  $N/1$  NaOH solution containing 0.001 per cent.  $NH_3$ , but differing in the content of sodium chloride. It should be noted that each figure in the second column includes 80-90 mg., due to the water vapour.

TABLE I.

NaCl, g.-equiv./l.	Weight of Fog + Water Vapour mg.	Found in Fog.	
		HCl (free), mg.	$NH_3$ (as $NH_4Cl$ ), mg.
0	467	35.9	0.64
1.0	457	37.0	0.64
2.0	389	33.4	0.65
3.0	310	28.4	0.65
4.0	217	18.9	0.66
5.0	140	12.0	0.66

The figures in the foregoing Table clearly indicate that as the fog obtained in a standard run gets thinner the amount of acid which it contains falls off steadily, whereas there is no sign of decrease—there is in fact a slight increase—in the amount of

ammonia carried over as ammonium chloride. It seems reasonable to conclude that the hydrogen chloride carried over depends on the water content of the fog droplets and that if the water-vapour pressure of the liquid in the fog-chamber could be reduced much further, nuclei of ammonium chloride would still be produced which, however, would be both dry and neutral.

Observations confirmatory of those in Table I. were obtained with triethylamine as the volatile alkali instead of ammonia.<sup>3</sup> In the series detailed in Table II. the air-HCl stream was passed in each case through a solution which was 0.5N as regards sodium hydroxide and contained 0.0009 per cent. triethylamine. The solutions, however, were progressively richer in sodium chloride.

Here again, as the water-vapour pressure of the solution in the fog-chamber decreases the free acid carried over in the standard run falls steadily, whereas the quantity of amine tends to rise.

TABLE II.

NaCl gm. — equiv./lit.	Wt. of Fog + Water Vapour (in mg.).	In Fog.	
		HCl Free mg.	Amine mg.
0	524	36.7	0.65
1.0	459	34.7	—
2.0	385	30.7	0.66
3.0	297	24.4	—
4.0	182	14.8	0.67

A relevant qualitative observation may also be recorded. A dried air-HCl stream was passed through a 50 per cent. NaOH solution containing 0.001 per cent.  $NH_3$ , then through two sulphuric acid bubblers and then through water. Nothing was

visible above the sodium hydroxide solution, but fog appeared in the water vessel. It contained no detectable free acid.

The foregoing evidence certainly supports the view that the primary event in the production of the fogs is the formation of nuclei of ammonium chloride followed by the condensation of water on these nuclei, giving a solution of salt. Only then does the absorption of hydrogen chloride begin. It is true that ammonium chloride is usually regarded as non-deliquescent, but the description is not an absolute one, for the possibility of deliquescence depends not only on the nature of the salt

<sup>2</sup> Jackson and Philip, *loc. cit.*<sup>1</sup><sup>3</sup> Banfield, *unpublished experiments*.

but also on the vapour pressure of its saturated solution and on the relative humidity of the surrounding atmosphere. Further, when the salt is in an extremely finely divided state, as in the present case, and has therefore a relatively large surface exposed, the rate of adjustment of equilibrium between the salt and the water vapour in the surrounding atmosphere will be very high. The experiments of Owens<sup>4</sup> on the conditions of deliquescence of minute crystals exposed to air of different relative humidity have shown that in the case of such salts as sodium chloride and ammonium chloride there is, in fact, a rapid adjustment of equilibrium.

<sup>4</sup> *Proc. Roy. Soc.*, 1926, 110A, 738.

### GENERAL DISCUSSION.

**Mr. C. F. Goodeve** (*London*) said: Professor Philip and his co-workers have been studying a very interesting type of mist and have developed a satisfactory explanation, involving the formation of a nucleus of ammonium chloride. It is to be hoped that they will now put their theories to a quantitative test. Some of the ways in which this can be done have been indicated in a paper by Dooley and myself.

It seems likely that the hydrochloric acid mist formed under the conditions of their experiments was in equilibrium with the vapour over the solutions which they used. Neglecting the effect of curvature, the vapour pressure of a solution of hydrochloric acid, as indicated by the 2nd and 3rd columns in Table I. should be the same as that of the NaCl-NaOH solution given in column 1. I have calculated the vapour pressures of these solutions (by adding the vapour pressure lowering of each compound) and in general have found that there is not good agreement between the values so calculated. It seems that there may be some disturbing factor present in their experiments.

No explanation has been given of the constancy of the ammonia content in the mists (last column, Table I.). It seems that this may be due to either or both of two causes. If the reaction between HCl and ammonium in the gaseous phase is very fast, the concentration of ammonia will be negligibly small. The amount appearing in the mist will therefore be governed by the rate of evaporation of ammonia from a solution of a certain strength into a gaseous space free from ammonia. This rate will probably be independent of the sodium chloride concentration and, therefore, a constant value is to be expected. On the other hand, the amount of ammonia in the mist is 80 per cent. of the total originally present in the liquid, and, as the rate of evaporation is probably directly proportional to the concentration of ammonia, a smoothing out of any variation would result from its deficiency.

The condensation of water and hydrogen chloride on the ammonium chloride nuclei must occur simultaneously as the vapour pressure of water on the droplet must always be below that of the solution before it is able to take up more water.

**Mr. J. H. Coste** (*Teddington*) said: The concentration of HCl in the fog water seems to have been fairly constant around 8 per cent., with a tendency to be greater in the fogs containing less ammonium chloride, suggesting that the droplets when formed absorbed a proportion of HCl, mainly determined by the concentration of gas, but also by the concentration of chlorides already existing in the droplets. Wright and I found that hydrochloric acid alone evaporated into nucleus-free air did not produce nuclei, which could be counted in the Aitken counter, although Helmholtz found that it did produce the "blue" cloud when mingled with steam issuing from a jet.

**Professor J. C. Philip** (*London*) said, in reference to Mr Goodeve's suggestion of some disturbing factor in the experiments: The results of these experiments, carried out under specified and controlled conditions, were perfectly definite and regular, and the want of agreement between the calculated vapour pressures was probably due to the uncertainty of the assumptions underlying the calculations.

He agreed with Mr. Goodeve's view that the amount of ammonia in the mist would be governed by the rate of evaporation of ammonia from the alkaline solution. It was probable, however, that the escaping tendency of the ammonia would, if anything, increase with the sodium chloride concentration, and this would account for the slight rise in the figures of the last columns in Tables I. and II.

As to the contention that the condensation of water and hydrogen chloride on the nuclei must occur simultaneously, the experiments indicated that a dry ammonium chloride mist (haze) would carry no free hydrogen chloride and hence it seemed fair to conclude that the absorption of water (it might be to some minimum extent) must precede the absorption of any hydrogen chloride. Subsequent to this the absorption of water and hydrogen chloride would no doubt go on simultaneously.

In reference to Dr. Coste's experiments with hydrochloric acid, it was perhaps of interest to record that in his (Professor Philip's) laboratory also it had been confirmed that strong hydrochloric acid did not fume in moist air, freed carefully from dust and ammonia.

---

## SORPTION OF FOGS BY LIQUIDS.

By H. REMY (*from experiments with W. SEEMANN, A. PANCERAM and H. FRIEDLAND*).

*Received in German (18th March, 1936), and translated by*  
JAMES COLVIN.

The factors which influence the sorption of suspended matter on passage through liquids, filters or, even, empty vessels are, firstly, *sedimentation*, and, secondly, the collisions of the suspended particles with the walls or with the surrounding medium; the latter may be conditioned either by the individual movement of the particles (Brownian motion) or by the *turbulence* of the gas transporting them.

For suspended matter (such as the sulphuric acid fogs we have investigated), Brownian motion may be excluded at once as a decisive factor since, with particles of the diameter shown by this fog ( $10^{-4}$  cm.), it is far too slight relative to the observed decrease in concentration.<sup>1</sup> On the other hand various observations have been made which suggest that in such fogs sedimentation plays an essential part in the decrease in concentration on passing through the sorption apparatus; for example, damp fogs are less absorbed by solutions, the higher the concentration of the solution, and consequently the lower its vapour pressure;<sup>2</sup> again, the decrease in concentration of the fog in passing through a wash-bottle depends almost linearly on the reciprocal of the streaming velocity, *i.e.*

<sup>1</sup> Cp. H. Engelhard, *Z. Elektrochemie*, 1925, 31, 590.

<sup>2</sup> H. Remy and K. Ruhland, *Z. anorg. Chemie*, 1924, 139, 51; *cp. also* A. Winkel and G. Jander, *Schwebstoffe in Gasen*, p. 72 f. (Stuttgart, 1934)

on the time taken to traverse the wash-bottle.<sup>3</sup> The experiments communicated here show, however, that this interpretation is not valid. Under experimental conditions such as we employ, sedimentation plays, at most, a quite subordinate part in the decrease in concentration of the fog. On the other hand, our experimental results are in complete agreement with the assumption that the essential factor is the turbulence of the transporting gas.

The experiments show that the dependence of the fall in concentration of the fog on the height of the layer of liquid through which it is bubbled is given accurately by assuming that the contact of the particles with the liquid depends solely on turbulence, and that sedimentation plays no part. The different sorptive action of solutions and pure water is therefore not to be attributed to an effect on the sedimentation velocity (as a consequence of reduction in the size of the particles by loss of water). Moreover, the dependence of the sorption on the streaming velocity in our experiments must be ascribed not to the influence which the time taken to pass through the sorption apparatus has on the amount of sedimentation, but to the dependence of the bubble size on the streaming velocity.

### I. The Dependence of the Decrease in Concentration of the Fog on the Height of the Layer of Liquid through which it is Bubbled.

If a gas bubble carrying a fog rises with uniform velocity through a liquid, the number of particles coming into contact with the enclosing liquid as a consequence of turbulence within the bubble in the time interval  $dt$  (the time required to travel the distance  $ds$ ) is proportional to the number of particles in unit volume. The concentration decrease in the fog is thus given by the equation:

$$-dc = a \cdot c \cdot ds,$$

where  $c$  is the concentration and  $a$  is a proportionality factor. Assuming uniform turbulence (by maintaining constant experimental conditions), the concentration decrease produced by traversing the interval  $s$  is

$$\int_{c_1}^{c_2} \frac{dc}{c} = \int_0^s a \cdot ds = -\ln \frac{c_2}{c_1} = a \cdot s.$$

$$(1a) \quad \frac{c_2}{c_1} = e^{-as}; \quad (1b) \quad c_1 - c_2 = c_1(1 - e^{-a \cdot s}).$$

The difference between the concentration,  $c_0$ , of the fog on entering the sorption vessel and the concentration,  $c_s$ , on leaving was measured. This measured decrease in concentration consists of (1) the decrease  $c_0 - c_1$ , which the fog undergoes from the moment of entry to the moment at which it begins to rise with the gas bubble through the fluid, (2) the decrease  $c_1 - c_2$ , whilst it ascends through the liquid, and (3) the decrease  $c_2 - c_s$ , which ensues as the upper part of the sorption apparatus, where there is no liquid, is traversed.

$$c_0 - c_s = (c_0 - c_1) + (c_1 - c_2) + (c_2 - c_s) \quad . \quad . \quad . \quad (2)$$

If the experimental conditions, apart from the height of the column of fluid are kept constant, then

$$c_0 - c_1 = c_0 b_1, \quad c_1 - c_s = c_s b_2,$$

<sup>3</sup> H. Remy and C. Behre, *Kolloid Z.*, 1935, 71, 129; H. Remy and W. Seeman, *Kolloid Z.*, 1935, 72, 3.

where  $b_1$  and  $b_2$  are constants dependent on the experimental conditions. Substituting these in equation (2), and combining with equations (1a) and (1b), we obtain :

$$\begin{aligned} c_0 - c_s &= c_0 \cdot b_1 + c_0(1 - b_1)(1 - e^{-as}) + c_0(1 - b_1)b_2 \cdot e^{-as}. \\ \frac{c_0 - c_s}{c_0} &= 1 - e^{-as}(1 - b_1 - b_2 + b_1b_2) \\ -\ln\left(1 - \frac{c_0 - c_s}{c_0}\right) &= as + \ln\left(\frac{1}{(1 - b_1)(1 - b_2)}\right). \end{aligned}$$

Transforming from natural to common logarithms, and expressing the concentration decrease as a percentage of the initial concentration, we obtain

$$-\log\left(\frac{100 - A}{100}\right) = \alpha \cdot s + \beta, \quad (3)$$

where

$$A = \frac{c_0 - c_s}{c_0} \cdot 100.$$

Of the two coefficients,  $\alpha$  is a measure of the absorption occurring during passage through the fluid, whilst  $\beta$  permits the calculation of the fall in concentration of the fog before and after this process.

Fig. 1 shows how accurately the linear dependence of the expression

$$-\log \frac{100 - A}{100}$$

on the height of the column of fluid, demanded by equation (3) is verified in our experiments using fogs of sulphuric acid, with water as the sorbent liquid. If sedimentation played a decisive part during the ascent of the bubble through the liquid, a curve should have been obtained, since in such clouds a substantial initial increase in the sedimentation velocity can be observed.<sup>4</sup>

A preliminary condition for good reproducibility of measurement is that the cloud should be produced under the same atmospheric pressure as that at which it enters the liquid, and that fluctuations of pressure during an experiment are carefully to be avoided.

Equation (3) permits the determination of the concentration decrease which the fog undergoes whilst bubbling through the liquid, from a few experiments carried out with different heights of liquid. It makes

FIG. 1.—Dependence of the absorption of the fog on the height of the column of liquid through which it is bubbled.

<sup>4</sup> H. Remy, *Z. anorg. Chemie*, 1924, 138, 167.

possible the elimination of the other concentration changes consequent on passing through the sorption apparatus. Theoretically, experiments with two different heights of liquid suffice, although in practice a larger number are employed in order to exclude chance errors.

In equation (3)  $\alpha$  has the dimensions of reciprocal length. By multiplying  $\frac{1}{\alpha}$  by  $\log 2$ , we obtain the height of liquid column required to reduce the fog concentration in the bubble to one half. In the experiments included in Fig. 1, this height was 24.0 cm. ( $\alpha = 0.0125$ ,  $\beta = 0.017$ ).

Similarly by varying the height of the space which the fog has to traverse after passing through the liquid to the outlet of the sorption apparatus, that part of the concentration decrease occurring there may be determined. In the experiments of Fig. 1 this height was 5 cm. For a liquid column (water) of 10 cm. (measured from the orifice of the inlet tube),  $A$  was found to be 27.90 per cent., of which 3.24 per cent. was due to the concentration decrease in the fog prior to its ascent through the liquid, 24.20 per cent. to the decrease during passage through the liquid and only 0.46 per cent. to the decrease in the part of the sorption apparatus not filled with liquid. With a liquid column of 25 cm. under

FIG 2.—Dependence of the absorption coefficients  $\alpha$  and  $\beta$  on the concentration of the solutions used for absorption of the fog.

the fixed conditions, the concentration decrease above the liquid amounted to only 0.32 per cent. of the initial concentration in a total decrease of  $A = 50.29$  per cent. The concentration decrease which the fog experienced between the times of leaving the liquid and escaping from the sorption apparatus was thus relatively slight, whereas that which occurs up to the moment at which single bubbles begin to rise through the liquid, is by no means negligible.

## II. Sorption of Sulphuric Acid Fogs by Sulphuric Acid and by Caustic Potash Solution.

Our experiments have shown that equation (3) holds for both sulphuric acid and caustic potash solutions as absorption fluid, the co-

efficients  $\alpha$  and  $\beta$  being affected in approximately the same way by the nature of the absorption fluid. This is shown by Fig. 2. Clearly, therefore, for the coefficient  $\beta$ , the decisive factor is the decrease in concentration of the fog which takes place, during the *time of formation of the individual bubbles* by absorption on the liquid boundaries.

Under the experimental conditions of Fig. 2, using pure water as absorption liquid, the coefficients had the values  $\alpha = 0.0077$  and  $\beta = 0.089$ . Using 6.1 per cent. sulphuric acid,  $\alpha$  fell to 0.0046 and  $\beta$  to 0.050. Using 5 per cent. caustic potash solution,  $\alpha = 0.0025$  and  $\beta = 0.016$ . With further increase in concentration of the absorptive fluid, the rate of diminution of absorptive power fell off, as Fig. 2 shows. In Table I. are summarised the heights of the columns of liquid, by passing through which under the experimental conditions of Fig. 2 a fall in concentration of 50 per cent. is occasioned. (Half-value heights.) Thus 51 per cent. sulphuric acid possesses a five times smaller absorptive power, and 40 per cent. caustic potash solution, a  $6\frac{1}{2}$  times smaller absorptive power than pure water.

TABLE I.—HALF-VALUE HEIGHTS OF DIFFERENT ABSORPTION FLUIDS.

Absorption Liquid.	Water.	Sulphuric Acid.			Caustic Potash.		
		6.1 Per Cent.	11.9 Per Cent.	51.25 Per Cent.	5 Per Cent.	10 Per Cent.	40 Per Cent.
Half-value height in cm.	39.1	66.1	89.4	202	119	196	257

The concentrations of the solutions in Table I. were so chosen that the sulphuric acid solutions and the caustic potash solutions had the same specific gravity. This was done in order to test whether solutions of the same specific gravity possess equal absorption coefficients; they do not, and there is just as little agreement in absorptive powers of solutions of sulphuric acid and caustic potash when compared at equal viscosity, equal surface tension or at equal vapour pressure.

### III. Dependence of the Fog Absorption Coefficients on the Streaming Velocity of the Fog.

The results communicated in the two preceding sections were obtained using a streaming velocity of 0.2 litres per minute. The absorption fluids were contained in vertical glass tubes of 3.6 cm. width and of different lengths.

A second series of experiments was carried out at *different streaming velocities*, using Drechsel flasks as absorption vessels. Table II. clearly shows that  $\alpha$  is dependent on the streaming velocity. It increases almost linearly with the reciprocal of the streaming velocity, *i.e.* with the reciprocal of the streaming velocity the bubble size decreasing<sup>1</sup> correspondingly. The dependence of  $\alpha$  on the streaming velocity is thus brought about by the fact that the size of the gas bubble in which the fog rises through the absorption liquid, is dependent on the streaming velocity. This cannot be ascribed to the fact that the amount of sedimentation of the fog is affected by changing the streaming velocity, since

<sup>1</sup> H. Remy and W. Seemann, *Kolloid Z.*, 1935, **72**, 283.

in contrast to  $\alpha$ , the coefficient  $\beta$  exhibits *no* such dependence on the streaming velocity, as would necessarily become apparent, if the concentration decrease were dependent to any real extent on sedimentation, since the time taken for the fog to pass through the sorption apparatus was varied ten-fold.

TABLE II.—THE ABSORPTION COEFFICIENTS  $\alpha$  AND  $\beta$  AT DIFFERENT STREAMING VELOCITIES OF THE FOG.

Streaming Velocity in Litres Per Min.	0.1.	0.133.	0.2.	0.4.	1.0.
$\alpha$ . . . . .	0.0301	0.0249	0.0192	0.0113	0.0076
$\beta$ . . . . .	0.04	0.05	0.02	0.04	0.04

The preceding statements support the view that the  $\beta$ -values are determined essentially by the concentration decrease of the fog before it bubbles through the liquid. The possibility of sedimentation after passage through the liquid was excluded in the experiments summarised in Table II., by keeping the empty space in the wash-bottle as small as possible (13 c.c.). If this small volume is exceeded to any considerable extent, sedimentation in this space may occur at low streaming velocities and affect the value of the sorption found under these conditions.

### GENERAL DISCUSSION.

**Mr. C. F. Goodeve** (*London*) (*communicated*): Remy's attempt to distinguish between sedimentation on one hand, and Brownian motion and turbulence on the other, does not seem to have a very good basis. One usually considers that Brownian motion is quite distinct from the other two factors. If one increases the particle size and mass, the removal by sedimentation *and* by turbulence increases very rapidly, whereas the removal by Brownian motion decreases. If this fact is agreed, the conclusions that appear in the second and third paragraphs are not valid.

It does not seem to be very useful to choose the complicated conditions which arise in bubbling a fog through a liquid. This is borne out by the fact that Professor Remy's mathematical equations show that there is no agreement between the absorbing power and any one of the physical or chemical properties of the absorbing liquid. It would be much better to choose simpler conditions such as occur when one passes a fog over a liquid surface at known velocities under reproducible conditions. Experiments in an apparatus of this type are described in a later paper to this discussion by Dooley and the speaker.

**Dr. N. Fuchs** (*Moscow*) (*communicated*): I regret very much that I could not become enlightened personally as to the sense in which Remy uses the word "turbulence." It could hardly be used in the strict hydrodynamical sense, since within air-bubbles of some millimetres size the turbulent state could only be attained at such flow-velocities of the air as are practically impossible in the case considered. It seems therefore that Remy means by "turbulence" the irregular motion of the air within the bubbles which leads to continual intermixing, and to uniform distribution of the mist contained in them. If this is so, the exponential law of absorption of mists by liquid layers of different height found by Remy must hold good independently of the actual mechanism of the adsorption.

The intermixing of the mist cannot, however, by itself force the droplets to reach the walls of the bubble. For this the droplets must leave the

flow-lines of the air directed tangentially to the walls, which is possible under the action of three factors only (assuming the droplets are uncharged), viz., Brownian movement, gravity and centrifugal force. It seems that Remy has in view the latter. It is, however, easy to see that the effect due to centrifugal forces is small in comparison with sedimentation in the case considered here.

Near the walls of the bubble the droplets move under the action of centrifugal force with velocity  $w = mvB/r$  where  $m$  and  $B$  are the mass and the mobility of the droplets,  $v$  velocity of air-flow in the bubbles,  $r$  their radius. The velocity of fall of the droplets is equal to  $mgB$ .

Assuming  $r = 0.4$  cm. (the average size of air-bubbles in Remy's experiments) we come to the conclusion that both effects will be equal at  $v = 20$  cm./sec. It is hardly possible to admit the existence of such flow-velocities within air-bubbles of such dimensions.

It seems, therefore, that sedimentation must play the chief rôle in the absorption of relatively coarse aerosols by liquids. It is, however, clear that sedimentation accompanied by continuous intermixing of the mist, now under consideration, is substantially different from sedimentation in still air, although the rate of settling at a given concentration of the mist should be practically equal in both cases. The only difference is that in the second case the rate of settling is constant (assuming the iso-dispersity of the mist and the absence of coagulation), and in the first it changes exponentially with time.

This conclusion could be verified quantitatively if the exact size of the droplets in the experiments of Remy were given. Assuming  $1\mu$  to be for the radius of droplets and 8 mm. for the diameter of the bubbles we can calculate that in 5 sec. about 20 per cent. of the mist will be absorbed owing to sedimentation.

Remy says later that if the absorption were caused by sedimentation of the mist then, according to his earlier experiments, there would be an acceleration of absorption during the rising of the bubbles. This statement seems to me not quite correct, since the time during which the bubbles move through the liquid in Remy's experiments<sup>1</sup> is so short (8 sec.) that there cannot be any perceptible coarsening of the mist.

Professor H. Remy (Hamburg), in reply, said: Removal by Brownian motion was excluded in my experiments by the particle size. The only possible causes of removal therefore, were sedimentation and turbulence. In the case of sedimentation we must distinguish between what happens during the rise of the bubble through the liquid and what happens in the liquid-free space of the absorption apparatus. The experiments described in the first and second paragraphs, exclude the influence of the latter effect; those in the third paragraph prove also that sedimentation within the bubbles has had no essential influence on the removal of particles since, with increasing of the streaming velocity, the times of formation of the bubbles decrease from 0.15 to 0.03 sec. The coefficient  $\beta$  in the experiments of the Table II. must therefore decrease considerably, if the removal of particles had been caused only by sedimentation, whereas, if turbulence had been the essential factor,  $\beta$  would be constant, because in this case the decrease caused by the shorter time would be paralysed by the increasing of the turbulence caused by the higher velocity of the air current. The word "turbulence" signifies the irregular motion of the air within the bubbles.

The "complicated" conditions of our experiments were given by the problems before us; we were not only studying the question discussed in this paper but a number of other questions, the results of which will soon be published in the *Kolloid Zeitschrift*.

It is true as Dr. Fuchs says, that my experiments do not decide what is the nature of the forces moving the particles through the air film in the

<sup>1</sup> Remy, *Kolloid. Z.*, 1935, 72, 285.

neighbourhood of the bubble wall ; as I have said in my paper, this question is as yet unsettled.

In the experiments of the first paragraph, the volume of bubbles was 0.48 c.cm., the initially falling velocity of the particles on entering the absorption apparatus was  $3.5 \times 10^{-3}$  cm./sec. If sedimentation only, without turbulence in the bubbles had taken place, the decrease of concentration in 8 secs. would have been 36 per cent., whilst 99.85 per cent. was found. According to earlier experiments,<sup>3</sup> the falling velocity of the mist particles increases initially proportionally with time. Consequently, the decrease of concentration caused by sedimentation, must follow an equation of the form  $-dc = (a_1 + a_2t)c \cdot dt$ , instead of  $-dc = a \cdot c \cdot dt$ . These questions will be discussed in the above-mentioned forthcoming papers.

## FOG ALONG THE MEUSE VALLEY.

By J. FIRKET, Professor at the University of Liège.

*Received 31st March, 1936.*

From the 1st to 5th of December, 1930, a thick fog covered a large part of Belgium, along the Meuse (flowing from W.S.W. to E.N.E.), between Liège and Huy, about 15 miles above it. A large number of people were injured ; several hundred were severely attacked with respiratory troubles, and 63 died on the 4th and 5th December, after only a few hours of sickness. Many head of cattle had to be slaughtered. On the 6th of December the fog disappeared ; the respiratory troubles improved and, in general, rapidly ceased. Public opinion was deeply moved, not only in Belgium, but also in neighbouring countries. Wherever fogs of several days duration are frequent, public authorities were anxious to know the causes of this catastrophe and several delegates were sent to the spot. This apprehension was quite justified, when we think that, proportionally, the public services of London, *e.g.*, might be faced with the responsibility of 3200 sudden deaths if such a phenomenon occurred there.

A public enquiry was opened on 6th December and a group of five Liège University professors, Messrs. Dehalu, Schoofs, Mage, Batta and Firket, brought to this question their special knowledge of meteorology, toxicology, industrial chemistry and pathology. These experts had at their disposal the most complete means of investigation because the examining magistrate could require autopsies and have all doors and documents opened to him.

There follows an abstract of the objective statements and interpretations to which the experts came.

**Medical Observations.**—All the sick people felt a retrosternal pain spreading along the edge of the ribs ; they all had fits of coughing, dyspnoea of a paroxysmic and expiratory character such as asthma, or real polypnea, although the latter was less frequent.

Among those in whom asthma was particularly severe, or who previously had frequent asthmatic bronchitis, or even who had cardiac insufficiency or myocarditis, or again who received anti-asthmatic treatments too late, the respiratory troubles were complicated by cardio-vascular collapse, marked by a rapid pulse, pallor, cold extremities, profuse per-

spiration and sometimes, when it had been looked for, dilation of the heart. In the sick, whose respiratory troubles did not consist in attacks of asthma, but in quickening of the rhythm of breathing, cyanosis was observed, as well as a tendency to frothy sputum.

About fifteen autopsies with microscopical examinations of tissues and spectroscopical or spectrographical analyses of blood, and also toxicological analyses of all organs were performed. The histological examinations showed that noxious products had been inhaled in the last hours of life, and had brought on a local and superficial irritation of the mucous membrane of the respiratory ducts exposed to the air inhaled. The microscopical sections of the lungs showed, in addition, the inhalation of fine particles of soot even as far as the pulmonary alveoli.

It is to be noted that the first symptoms, shown by the first patients, began in the afternoon of the third day of fog, which had then been at its maximum opacity for several hours. On the other hand, on the 6th of December, when the fog dispersed, respiratory troubles grew rapidly better, so that death took place only on the fourth and fifth day of the fog. Moreover, the enquiry established that the first symptoms, marked by the first patients treated, were observed at the same time along the whole of the attacked region, *i.e.*, for about 15 miles. It was thus impossible to discern the "diffusion" of a noxious gas in the atmosphere of the valley.

**Meteorological Conditions.**—The meteorological conditions existing from the 1st to 5th of December were as follows: Fog, starting on December 1st, anticyclonic conditions persisted, characterised by high atmospheric pressures and feeble wind, generally in an easterly direction, *i.e.*, blowing upstream and slowly spreading smoke coming from the city of Liège and the large factories above it into the narrow valley. Moreover, a phenomenon of inversion of temperature established at about 90 yards from the soil a kind of atmospheric ceiling, lower than the hills bordering the valley and thus transformed the valley itself into a tunnel. The total volume of this tunnel could be approximately calculated therefore. Fine solid particles, mainly made of soot, had fallen during the five days of fog into the almost motionless atmosphere. Most of them—varying from 2 to 6  $\mu$ —must have taken two or three days to fall from the height of 40 to 70 yards, if we apply Stokes's law; 60 yards is the average height of the manufactory chimneys or the industrial region in question.

The conjunction of meteorological conditions observed in the beginning of December, 1930, is quite unusual in this district. During the last thirty years, fogs lasting more than three days have only occurred five times, always in winter (1901, 1911, 1917, 1919 and December, 1930). It is interesting to note that, because of the war, industry was not very active in 1917 and 1919, while in January, 1911, serious accidents occurred similar to those of 1930, but with attacks chiefly on cattle.

**Chemical Analyses.**—Since the fog itself could not be analysed, the chemists sought to ascertain the nature of the gas by analysis of deposits on the soil, but this was unsuccessful since they could not, in this way, distinguish the toxic substances which had been deposited only during the recent foggy period.

They established the balance of the gases which had polluted the atmosphere of the valley, by taking into account the activity of the factories of the region, as well as the number of domestic fires. For the factories, the raw materials used during the five days of fog and in many cases, intermediate products of gas and smoke were examined; very few results were available from the staffs of the factories. For the evaluation of domestic pollution, it was assumed that every house burned about 33 pounds of coal daily, the volatile sulphur in this being taken as about 1 per cent. The total number of houses was furnished by the local councils, so that approximate figures of  $\text{SO}_2$  evolution could be arrived at; however, these figures must be considered as minima, since the basic figures of 33 pounds and 1 per cent. sulphur are relatively low.

The chemists succeeded in fixing, among about thirty substances found to be polluting the atmosphere, the maximum concentrations reached by carbon monoxide, carbon dioxide, nitrous gases, sulphur dioxide, hydrofluoric acid. They concluded that the  $\text{SO}_2$  evolved in the presence of oxidation catalysts, such as ferric and zinc oxide, in the fog, the  $\text{SO}_2$  must have been partly transformed in sulphuric acid.<sup>1</sup>

The data thus collected and the toxicological analyses having been quite negative, the pathologists and industrial chemists sought to ascertain which of the thirty chemical substances left might have produced the medical symptoms described; only those had to be considered which cause irritation of the respiratory or other mucous membranes. They therefore excluded the lack of oxygen and carbon dioxide, carbon monoxide and divers solid dusts, the latter because of unsuitable anatomical observations. They also excluded a series of noxious gases which could not have reached their threshold of toxicity, according to the balance established previously by the chemists, or because they would have brought on other symptoms or lesions than those pathologically observed.<sup>2</sup>

Very few substances remained. They must have been either in a gaseous state, or dissolved in very fine liquid or solid particles which might have adsorbed toxic gases. Among such substances, maybe  $\text{SO}_2$  and its products of oxidation, HF, nitrous or ammoniacal vapours, HCl. Cold and dense fog could not of itself bring about death within the limits of the time observed, since the fog was just as opaque over all the east of Belgium, and should have brought about similar accidents, but this was not the case.

Now, neither nitrous vapours, nor ammoniacal vapours, nor hydrochloric acid had existed in the atmosphere in sufficient quantity to produce the accidents observed along the entire extent of the unfortunate valley, at every part of it, and at the same moment. Again, hydrofluoric acid had been emitted by one single chimney, located about the middle of the region in question, but this could not be responsible, since no signs of its diffusion in the atmosphere were noted when taking records of the precise moment when the first patients felt their first symptoms all along the valley;

<sup>1</sup> The fifteenth annual report of the investigation of atmospheric pollution for the year ended 31st March, 1929, said (page 2): "A striking fact which emerged very early in the work was that in the place of experiment (Holborn) at all events, sulphur trioxide is not a normal constituent of the atmosphere; it appears only during fog." This result was at the time "somewhat unexpected," to the British observers who had been accustomed for fifteen years to analyse the atmosphere.

<sup>2</sup> The following examples will give an idea of the interpretation given by the experts concerning the calculations of industrial chemistry.

Consider the possibility of a lack of oxygen in the air of the valley, due to surcharge of the atmosphere with large amounts of gases of combustion during the foggy days. An approximate idea of the maximal amount reached by these gases of combustion in the valley is ascertained as follows. The total volume of the valley is estimated at  $3 \times 10^9$  cubic metres (about 30 km. long, 1 km. wide and 100 m. high). If the gases of combustion had completely surcharged this atmosphere, none being diffused outside, they would not, according to the chemical balance, have exceeded the following maxima:  $42 \times 10^6$  cubic metres for  $\text{CO}_2$ ,  $10^6$  for CO,  $16 \times 10^7$  for nitrous gases,  $10^5$  for  $\text{SO}_2$ , i.e., a total of  $2031 \times 10^6$  cubic metres. The oxygen contained in the air of the valley would not have decreased by more than 10 per cent., i.e., it would still have constituted at least 19 per cent. of the atmosphere, whilst it was long ago proved by Haldane and Smith that life is perfectly possible in an atmosphere containing only 15 per cent. and even less of oxygen.

Again, if all the  $\text{CO}_2$  had remained in the valley during the fog (supposing, as is unlikely, that no diffusion was possible) the maximum increase in  $\text{CO}_2$  for the entire volume of the valley would be less than 1.5 per cent., whereas we know that man can live without discomfort in an atmosphere containing 2 per cent.

Moreover, the medical symptoms were not those usually observed in the case of need of oxygen, neither those of an intoxication by  $\text{CO}_2$ .

it could not, however, be absolutely excluded as a secondary factor acting in the near neighbourhood of the factory which issued it.

There then remained only  $\text{SO}_2$ , which issues in the largest abundance in the whole valley as a result of burning coal. It is moreover probable that part of the  $\text{SO}_2$  (but it cannot be said, even approximately, how much) was oxidised into sulphuric acid, the threshold of toxicity of which is much lower. From the table, we can conclude that only the sulphur bodies have been spread in the whole valley, in amount sufficient to produce accidents among those exposed to the polluted atmosphere for several hours, while for all the other noxious gases, the amount established by calculation always remained far below the threshold of toxicity.

Sulphur dioxide probably existed in the air in amount insufficient to be noticed by its characteristic smell, but even in such small quantities, its toxicity for human beings may be very strong. It has been shown, *e.g.*, by Lehman and Hess that amounts of  $\text{SO}_2$  from 170 to 640 mgs. per cubic metre and dissipated after half an hour or even one hour may be fairly harmless, although even as little as 20 mgs. per cubic metre may cause serious trouble after several hours.

Moreover, only from the action of sulphur pollution can we explain

CALCULATIONS ESTABLISHED FOR 25 KMS. (about 15 MILES) of the VALLEY,  
FROM HUY TO A POINT NEAR LIÉGE.

Name of Substance.	Rate of Toxicity after several Hours Exposure.	Maximum Amount which could have been reached after 1 Day of Fog.	Maximum Amount which could have been reached after 4 Days of Fog.
$\text{CO}_2$	2 per cent in volume	About 0.4 per cent. in volume	About $1\frac{1}{2}$ per cent. in volume
CO	$\frac{1}{2}$ f. 1000	About $\frac{1}{2}$ f. 1000	About $\frac{1}{2}$ f. 1000
$\text{NO}_2$	12 to 16 cgs. for 1 m. <sup>3</sup>	1 to 2 mgs. f. 1 m. <sup>3</sup>	4 to 8 mgs. for 1 m. <sup>3</sup>
HF	Unknown; it must be about 4 mgs for 1 m. <sup>3</sup>	0.08 mg. f. 1 m. <sup>3</sup>	0.3 mg. f. 1 m. <sup>3</sup>
$\text{SO}_2$	20 to 30 mgs. for 1 m. <sup>3</sup>	25 mgs. f. 1 m. <sup>3</sup>	100 mgs. f. 1 m. <sup>3</sup>
$\text{H}_2\text{SO}_4$	4 mgs. f. 1 m. <sup>3</sup>	36 mgs. f. 1 m. <sup>3</sup> (Supposing the whole	152 mgs. f. 1 m. <sup>3</sup> $\text{SO}_2$ would have been oxydated.)

why the accidents appeared simultaneously along the entire valley; several hours of breathing such an atmosphere, where the noxious gases existed in relatively low amount, were necessary to provoke respiratory troubles. Several hours were also needed before the lower parts of the atmosphere, near the soil, were charged with sufficient quantities of sulphur bodies (mainly adsorbed on sooty particles; the latter, issued from the high factory chimneys, could only reach the soil after several days). Moreover, a certain time had to elapse before the oxidation factors transforming  $\text{SO}_2$  into  $\text{SO}_3$  could act.

From the pathological standpoint, the two types of respiratory troubles noticed favour to a certain extent the idea that the noxious gases were sulphur dioxide and sulphuric acid. The physicians of the valley had all noticed, during the foggy days, (a) symptoms due to direct irritation of the mucous membranes with reflex symptoms (asthma and subsequent vascular collapse), certainly caused by a state of alkalosis in the blood, (b) on the other hand, symptoms of polypnaea with edema of the lungs, *i.e.*, action of noxious gases on the wall of pulmonary alveoli and very probably anoxaemia with acidosis of the blood. It is now well known<sup>2</sup> that irritant gases are

<sup>2</sup> Especially after the research of Henderson and Haggard.

mainly of two types according to the region of the respiratory ducts where they act: the soluble and dense vapours like  $\text{H}_2\text{SO}_4$  in fine droplets will be fixed by the superior respiratory ducts, trachea or bronchi, while the lighter and less soluble gases, i.e.,  $\text{SO}_2$  will penetrate into the deep cavities of the lungs and produce edema: in the first case, the clinical symptoms will be those of asthma; in the second, those of anoxaemia with acidosis.

Finally, from the geographical distribution of the gravely attacked patients and the dead, one could see that the rate of  $\text{SO}_2$  was higher at the extremity of the valley near Liège where factories and private houses are more numerous, than at the other end near Huy. The geographical conditions of the valley above Liège are really very unusual and unfavourable when a weak easterly wind and fog appear together.<sup>4</sup>

In conclusion, we believe that undoubtedly the conjunction during more than three days of the same exceptional meteorological conditions would cause the same accidents if the industrial and domestic fires are equally active. Our measurements led us to the idea that one-fifth of the  $\text{SO}_2$  issued in the valley came from domestic fires. Moreover, chemical analyses to control the pollution of the atmosphere in Liège itself (especially of sulphur bodies), showed that the latter reached a level in the city ten times higher than thirty years ago. The problems and the catastrophe here studied demonstrate once more the social and hygienic importance of questions connected with atmospheric pollution. In that field Great Britain is really the leading country.

*Liège, 27th March.*

<sup>4</sup>The extensive report of the question here summarised can be found in pages 260-335 of *Les problèmes de pollution de l'atmosphère*, by G. Batta, J. Firket and E. Leclerc. Edit. Georges Thone, Liège, and G. Masson, Paris, 1933 (462 pages).

### GENERAL DISCUSSION.

Professor Firket in introducing his paper, referred to a scale map of the Meuse valley.

Mr. J. H. Coste (*Teddington*) said: The concentrations of sulphur compounds suggested by Firket as possible in the air of the Meuse valley during the fog in question are much greater than we have found in London under any weather conditions. Most people, it is supposed, can smell  $\text{SO}_2$  when its concentration reaches 2 volumes per million, but it seems probable that sensitivity varies very much according to customary exposure; a member of my family who has never lived in a large town can smell  $\text{SO}_2$  in the white to pale yellow fogs we get in the semi-rural parts of the Thames valley, whilst town dwellers are probably less sensitive.

It seems probable that during bad fogs in industrial or crowded districts sulphuric acid is present in irritating amounts. In the fog of 23rd December, 1935, mentioned in my paper, the air, especially around the period of high  $\text{SO}_2$  concentration was very irritant, affecting both the respiratory passages and the thin skin around the eyes. The effect was not unlike one's sensation when evaporating sulphuric acid in small quantities in a room.

In an industrial district there would always be enough nitrous acid in the air in still weather for appreciable oxidation of  $\text{SO}_2$  to occur.

The evidence collected by the commission, which I read when the report was issued, was mainly circumstantial, but I think that an unusually big formation, with little dissipation, of sulphuric acid, was the most probable cause.

Dr. F. J. W. Whipple (*London*) said: The meteorological conditions described in Firket's paper are puzzling. It appears that there was

measurable wind throughout the period, and this seems at first sight inconsistent with the hypothesis that the air was practically stagnant in the valley. However, Firket has not given any information about the height of the Observatory where the wind was recorded, and it may be that the air current was persistent above the fog, which was confined to the valley. With a sharp inversion of temperature the upper air could glide over the top of the fog without dragging it along. It is perhaps important to notice that in a fog which is being cooled by radiation from the top and warmed by contact with the ground there is gentle convection and the temperature is nearly uniform. It is not justifiable to assume that smoke particles merely settle down through the fog, they are carried down by the convection currents.

It is difficult to believe that the deaths were due to breathing sulphur dioxide, since the conditions in the valley could hardly have been so bad as those which prevailed in the tunnels of the underground railway in London in the days of steam trains, where the sulphurous fumes were notorious, but conditions were not found unhealthy by the railwaymen. Is it not possible that some noxious product of the furnaces in the Meuse Valley has been overlooked?

**Dr. R. Lessing** (*London*) said that he had directed attention to the emission of sulphur oxides in the combustion of fuels <sup>1</sup> six months before the Meuse tragedy. In a later paper, <sup>2</sup> he had shown that the annual emission of sulphur oxides in Greater London was, at a low estimate 500,000 tons in terms of  $H_2SO_4$ . The reason why free  $SO_2$  or sulphuric acid was so rarely observed in the atmosphere was that it was readily neutralised by the lime or other basic dust always present in town air. During the first two or three days of the Meuse fog the lime particles settled out along with the soot and other solids so that later the sulphuric acid could not find neutralising material to act upon. Moreover, the high moisture saturation provided an ideal medium for the oxidation of  $SO_2$  to  $SO_3$  at a higher rate than in dry air.

**Mr. G. Nonhebel** (*Billingham*) (*communicated*): The statements by Professor Firket that 20-30 mg.  $SO_2/M^3$  and 4 mg.  $SO_3/M^3$  air may cause trouble after several hours leads to the question: "What are the safe upper limits for the  $SO_2$  and  $SO_3$  concentrations in the lee of a large modern power station burning coal at a peak rate of several thousand tons per day." We have found that up to 10 per cent. of the sulphur in the gases from a powdered fuel plant may be present as  $SO_3$ .

**Dr. S. R. Carter** (*Birmingham*) said: Although excessive fog in the Meuse Valley is the subject under discussion, the reverse question interests me, as on the occasions when I have visited Liège the atmosphere seemed to be remarkably clear considering that it is a large manufacturing town. Is the reason for this known?

# SULPHURIC ACID AS A DISPERSE PHASE IN TOWN AIR.

By J. H. COSTE AND G. B. COURTIER.

*Received 10th January, 1936.*

The sulphur in air is mainly present as sulphur dioxide but under some atmospheric conditions it has been found that air from which the sulphur dioxide has been removed still shows measurable sulphur acidity. The acid constituent can be retained on a suitably fine filter, but experiments made with asbestos, sintered glass, and cotton wool filters confirmed our opinion that methods involving such filters are unsuitable when the acidity is of the low order found in the atmosphere. Apart from the small possibility that the filtering material may itself yield on extraction either alkali or acid to water, it is likely to separate from air all but the very finest suspended matter. This may, and probably does, include all or almost all the acid which is present in other forms than gas or vapour, but it will in most cases include particles which are either basic and when treated with water will yield a liquid of  $p_H$  greater than 7, or will easily be attacked by strong acids with the liberation of weaker ones, *e.g.*, carbonic or silicic acids.

We have, therefore, sought a means of separating free sulphuric acid from the air in which it may be present, without mixing it with the many other matters held in suspension in air. Since sulphuric acid is a very hygroscopic substance we have sought to take advantage of this fact by inducing condensation of water vapour by cooling, which should increase the mass of droplets of sulphuric acid or other hygroscopic nuclei so as to enable them to fall to the bottom of a vessel.

## Experimental Methods.

Air which had been freed from sulphur dioxide was almost saturated with water vapour at room temperature and then passed through a flask immersed in ice. A condensate representing the greater part of the water content was obtained, which when sulphuric acid was found to be present, would have formed on nuclei of that compound in droplets sufficiently large to be retained in the flask. The condensate was almost free from dust and smoke particles, which passed through the flask and could be retained on a filter.

About 1000 litres of air were passed during 24 hours, yielding between 5 and 10 ml. of condensate. The  $p_H$  value was measured in the absence of carbon dioxide, and samples showing appreciable acidity were titrated with *N*/250 potash from a micro-burette using purified distilled water as the blank. In order to detect the presence of sulphates, 1 ml. of the condensate together with a drop of barium chloride solution was transferred to a watch glass and allowed to evaporate slowly on an electrically heated plate. Crystals of barium sulphate were observed, giving definite proof of sulphates in all samples showing acidity. Comparison with dilute standard solutions of sulphuric acid precipitated under the same conditions indicated that the acidity of the condensates could be attributed to sulphuric acid.

In the first experiments the compound of hydrogen peroxide and urea (Hyperol) was used for the absorption of sulphur dioxide. Hyperol is

more stable than free hydrogen peroxide in dilute solution and has a lower vapour pressure. Using a solution of about 1 per cent. in purified water and with two gas washers in series, it has been found, from extensive experience of sulphur determinations in air, that not less than 99 per cent. of the total absorption takes place in the first washer. Since this is true for the whole range of concentrations encountered, it can be assumed that with two washers gaseous absorption is virtually complete. Air passed through these washers yielded, on cooling, condensates with  $p_H$  values varying in different samples between 4.3 and 5.6. It was thought that there might be some possibility of sulphur dioxide being oxidised by hydrogen peroxide vapour in the gas phase with the formation of sulphuric acid, which would pass through the washers unabsorbed, and when deposited by water condensation might be considered as having been present in the air originally. Some further tests were therefore made using a solid absorbent having no appreciable vapour pressure. Broken pumice coated with lead peroxide, in U tubes, was found to be very efficient for the purpose, as air which had passed through these tubes yielded no acid to hyperol solution. When using lead peroxide for the preliminary removal of sulphur dioxide, the water vapour content of the air was raised nearly to saturation by passage through a wash tube, and when condensation was induced by cooling the water formed was found to be slightly acid as in the previous tests. The condensates obtained under these conditions had  $p_H$  values between 4.8 and 6.0. These values were rather higher than in the first series of tests but the difference can be attributed, at least in part, to the filtering action of the closely packed tubes.\* Further evidence that the presence of sulphuric acid was independent of oxidation in the reaction tubes was obtained after using potassium hydroxide solution for the absorption of sulphur dioxide. A tube of pumice chips was inserted to prevent the passage of spray, and a  $p_H$  of 5.0 was measured.

A sensitive test for sulphurous acid is the change in blue shade produced in water slightly coloured by starch-iodine. When the condensates obtained by the above methods were tested with this reagent there was no evidence of the presence of sulphurous acid, although this was readily detected in samples resulting from the direct cooling of air without previous removal of sulphur dioxide. It was established that oxidation in such solutions was not rapid, and the absence of sulphurous acid in the condensates confirmed that the methods for preliminary removal of sulphur dioxide were adequate.

The "Monax" glass used for the apparatus, when thoroughly cleaned, was not appreciably affected by the solvent action of cold water having a  $p_H$  of the order encountered during the experiments.

## Results.

The experiments were made, mainly in central London, under a variety of atmospheric conditions. The qualitative tests of the condensates obtained by the above methods consistently indicated the presence of traces of sulphuric acid, and the amounts were estimated to vary between 1 and  $20 \times 10^{-6}$  gm. per 1000 litres; the sulphur dioxide in the same samples of air varying between 0.10 and 0.50 ml. (equivalent to 440 and  $2200 \times 10^{-6}$  gm. sulphuric acid). The maximum amounts of sulphuric acid were usually registered in periods of calm and in foggy conditions, while the amounts were invariably small after rain. No exact relationship was established but, in general, conditions which favoured high sulphur dioxide content also favoured high sulphuric acid content. There was some evidence that

\* After the above was written, Mr. H. L. Wright found, in the course of further work with one of us on the nature of hygroscopic nuclei, that similar tubes packed with lead peroxide allowed only from 1/9 to 1/5 of the nuclei originally present in air to pass through, whilst the reduction in number of nuclei when air was passed through hyperol was of the order of 10 per cent.

the proportion of sulphuric acid was greater at ground level than at sixth floor level. Some observations made at an outlying northerly suburb showed that while the sulphur dioxide content was only 0.02 ml. per 1000 litres (equivalent to  $44 \times 10^{-6}$  gm. sulphuric acid) the amount of actual sulphuric acid was  $4 \times 10^{-6}$  gm.

From the experimental methods employed it may be concluded that the failure to retain the acid in the earlier absorbers with the gaseous sulphur dioxide was due to the existence of the sulphuric acid, probably associated with water, in aggregates of molecules—hygroscopic nuclei. Although the extraction of sulphuric acid in the condenser was not entirely complete, as was shown by the addition of an extra saturator and condenser, it did not appear that the total acid content was much greater than that stated.

### Discussion.

The presence of such very small proportions of sulphuric acid in air containing relatively large proportions of sulphur dioxide may be explained on other grounds than the slowness of oxidation of the dioxide. When it is considered that facts point to the most obvious oxidising agent—nitrous acid—as occurring in air mainly in a liquid, or at least non-gaseous, phase,<sup>1, 2</sup> it appears that oxidation must be rather slow.

Sulphuric acid, as formed, will rapidly pass almost entirely into a liquid phase, although action occurring between sulphuric acid and a steam jet near which a drop of the strong acid is brought can only be explained by the concentrated acid having an appreciable vapour tension.<sup>3</sup>

N. Fuchs and N. Oschman<sup>4</sup> in attempting to form stable aerosols of sulphuric acid found difficulty in overcoming the tendency of droplets to combine to form larger ones. They succeeded, however, by rapid dilution of concentrated aerosols with relatively dry air, in obtaining uniform aerosols containing droplets estimated at  $1.5 \times 10^{-6}$  cm. radius in relatively dry air, which is of the same order as that of the nuclei of Aitken<sup>5</sup> and the large ions of Langerin, which are considered as charged nuclei. A million of these per ml. of air would yield concentrations of  $\text{H}_2\text{SO}_4$  of the order we have found. One of us and Wright<sup>2</sup> found that the rate of disappearance of nuclei obtained by burning fuel containing sulphur or by projecting  $\text{SO}_2$  into air was very rapid, and this may be due as much to growth by absorption of water until the droplets are large enough to fall through the air with an appreciable velocity, as to recombination, although both these actions must go on. The tendency to form ammonium sulphate (ammonia is usually present in air), coalescence with heavy particles, including calcium carbonate (from building materials) and coke, must not be overlooked. Dusts collected in inhabited or industrial districts contain both alkaline and acid particles, these latter frequently being coke with an acid surface film, as shown under the microscope by the use of indicators. Frequently they contain sulphate.

The facts, generally, show that a considerable liquid phase of sulphuric acid droplets is very unlikely to occur in air; the conclusions,

based, it must be admitted, on circumstantial evidence of the Commission which reported on the Meuse Valley fog of 1st to 5th December, 1930, raise the strong presumption that when sulphuric acid becomes an important constituent of fog catastrophic disaster may be expected.

### Summary.

A method of investigating the sulphuric acid content of the air has been devised, which does not involve the use of filters. The free sulphuric acid content of London air has been shown to be of the order of  $1$  to  $20 \times 10^{-8}$  gm. per cubic metre.

This is of the order which would be expected having regard to the numbers of Aitken nuclei and the mass of sulphuric nuclei in artificially prepared aerosols of this acid.

### GENERAL DISCUSSION.

Mr. C. F. Goodeve (*London*) expressed incomplete agreement with Coste and Courtier in the usefulness of the apparatus they described, and he did not agree that sintered glass filters are unsuitable.<sup>1</sup> Such filters have been used to test the amount of sulphuric acid, in excess of the alkalinity, present in London's atmosphere on a number of occasions during January and February, 1934. The extreme simplicity of the filter method over any other method makes it well worth considering carefully from the point of view of routine observations. On the other hand the apparatus described by the authors requires careful watching and is slow with regard to the amount of air handled per hour.

It is agreed that the two methods might give slightly different results, but only if acid and alkaline particles exist independently in the atmosphere. There is no evidence at present to show whether or not this is the case, but the argument given in the paragraph below leads to the conclusion that it is unlikely.

Even if it is considered that the two methods do give different results, those obtained by the filter method would appear to have important practical advantages over those obtained by the method described by the authors. The importance of knowing the sulphuric acid content of the air is largely due to its action on building materials and on living tissues. This action will be partly offset by the alkaline particles and therefore the *net* acidity is of importance.

The speaker called attention to the important observations of Ellis<sup>2</sup> who found that, even in the presence of high concentrations of a sulphur dioxide, the sulphuric acid content of London air was immeasurable, except in the presence of fog. They found a maximum value of 0.62 volume parts per million (calculated as  $\text{SO}_4$ ). Some of the values obtained at University College during February, 1934, are shown in the table on next page.

The absence of sulphuric acid before fog particles are formed indicates that it cannot be considered as a *cause* of fog formation but rather as a contributing factor to the intensification of fog. The amount of sulphuric

<sup>1</sup> The use of the sintered glass filters is discussed later, p. 1220.

acid formed in flue gas is very small and the rate of oxidation in sulphur dioxide gas in the absence of liquid water is also small. Dr. Pinck (unpublished results) found that there was no oxidation in the presence of dry catalysts, such as iron oxides, even after a considerable period of time, but when water vapour was present sufficient to produce an adsorbed film over the catalyst, rapid oxidation at once took place. The formation of sulphuric acid in the atmosphere can take place by the condensation of water on nuclei (either alkaline or neutral), the subsequent solution of sulphur dioxide, and its rapid oxidation catalysed by the solid nuclei. If this is the case, there is no reason for the existence of independent alkaline particles in fogs and the two methods of analysis discussed above should give the same result.

Mr. J. H. Coste (*Teddington*), in reply, said: It is true, as pointed out by Mr. Goodeve that sintered glass is a good filtering medium for removal of dispersoids from air. In considering the useful work of Ellis (who used an asbestos filter as suggested to the Research Committee by Lambert of Oxford) I feel in the light of the certainty that acid and alkaline particles do exist together in air (a fact that Mr. Goodeve seems to doubt), that any method in which all the dispersoids are collected together is likely to yield erroneous results. Mr. Nonhebel has found that up to 10 per cent. of the sulphur in the gases from a powdered fuel plant may be present as SO<sub>3</sub>, the amount of accompanying water vapour being great. This would go into the air as droplets, which would only be neutralised by collisions with alkaline particles or absorption of ammonia. Again, any sulphuric acid formed by the action of nitrous acid would be in droplet form, and neutralisation in free air would be much slower and less likely than when air was forced through a filter which was also separating alkaline particles.

The offsetting effect of alkaline particles can only come into play if acid and alkali are in juxtaposition. In collections of rainwater, containing the solids brought down with it, I have found alkaline zones surrounding particles in an acid liquid; thus neutralisation does not always happen.

Mr. Goodeve's observations on fog are very interesting, and I agree with him that the presence of abundance of droplets of water with an accumulation of sulphur dioxide (and nitrous acid) which would occur in a town fog is likely to raise the sulphuric acid content from an infinitesimal to a measurable amount.

# THE INFLUENCE OF URBAN CONDITIONS ON THE CIRCULATION OF ELECTRICITY THROUGH THE ATMOSPHERE.

BY F. J. W. WHIPPLE.

*Received 30th March, 1936.*

Atmospheric electricity is a subject in which it is difficult to disentangle the influence of world-wide forces and of local conditions. In every situation there are a number of phenomena to be observed and correlated, and at present there is no observatory which can claim that all the relevant measurements are being made regularly, or even intermittently. Of the elements which can be recorded, potential gradient is by far the most frequently observed, but the interpretation of the changes in the value of this element is now known to be very complicated.

It has been realised for a long while that the fact that there is a gradient of potential is evidence for the existence of a charge on the ground, and of a complementary charge in the atmosphere. Normally the ground carries a negative charge, and the complementary charge is positive. Observations in balloons indicate that the potential gradient falls off rapidly with increasing height, so that the charge in the atmosphere is mostly at low levels. One way of regarding observations of potential gradient is that they are measurements of the space-charge in columns of the atmosphere.

Alternatively, attention may be concentrated on the flow of electricity. Owing to ionisation, the air is a conductor, and under the influence of potential gradient a current flows from the upper air to the ground. In a steady state the current must be the same at all heights. This rule is in accordance with observation, i.e. in individual ascents the product of potential gradient and conductivity has been found to be constant, as nearly as can be expected from the circumstances of the observations.

A fundamental problem in Atmospheric Electricity is to explain how this air-earth current, which prevails in fine weather in all parts of the world, is maintained. It is known that in the upper atmosphere there are layers of highly ionised air, of which the most important from the present point of view is the Kennelly-Heaviside layer at a height of about 100 km. The conductivity of this layer is so good that it must be at very nearly the same potential over all parts of the world.

If electricity flows downwards from the Kennelly-Heaviside layer in regions where there is fine weather, the supply must be maintained by upward currents predominating in regions where there is bad weather.

In fact, rain-clouds act as electrical machines pumping electricity up towards the K.-H. layer. Wormell has shown that the available estimates of the quantity of electricity exchanged between clouds and ground by conduction currents, by charged rain and by lightning are consistent with this hypothesis, which, it may be noted, does not involve any particular theory of the mechanism by which the separation of electricity in the clouds is produced.

The potential of the K.-H. layer being the same in all parts of the

globe, the current which flows towards the ground in any place must depend on the conductivity of the air, the current varying inversely as the effective resistance of the column of air between the ground and the Heaviside layer. The electricity is carried by ions, positive ions moving downwards and negative ions upwards; it is only by the current of positive ions that electricity is communicated to the ground, so that the strength of the air-earth current is proportional to the potential gradient and to the conductivity due to positive ions. This may be expressed otherwise by saying that the potential gradient is proportional to the current, and to the specific resistance of the air.

FIG. 1.

It will be seen that, according to the theory which has been sketched, the potential gradient at any time and place is

- (a) proportional to the potential of the K.-H. layer;
- (b) inversely proportional to the effective resistance of a column of the atmosphere;
- (c) proportional to the specific resistance of the air near the ground for positive electricity.

It is proposed to apply this theory to the interpretation of observations of the diurnal variation of potential gradient at Kew Observatory. For this purpose, we shall consider the diurnal variation during four summer months and four winter months in 1930 and 1931, during which there were continuous records<sup>1</sup> of the air-earth current at the Observatory.

<sup>1</sup> F. J. Scrase, "The Air-earth Current at Kew Observatory," *London Met. Office Geophysical Memoirs*, No. 58 (1933).

Fortunately, these short periods yielded diurnal variation curves which were true to type. These are shown in the second lines of Figs. 1 and 2. Both in summer and in winter there are two maxima and two minima in the course of the day.

The uppermost curves in the diagrams represent the diurnal variation of the potential of the Heaviside layer. These curves are not as speculative as might be supposed. It will be noticed that the absolute value of the potential is not involved, we are only concerned for the moment with proportional changes. Now, it will be realised that over the oceans there is no pollution, and no considerable systematic variation in temperature, so it may be assumed that at points far from land the total resistance of a column of the atmosphere is constant throughout the day,

FIG. 2.

and also the specific resistance of the air in the lowest layer. Accordingly, the changes in potential gradient are proportional to the changes in the potential of the Heaviside layer. Now, it was established by Mauchly that the changes in potential gradient over the oceans depended on Greenwich time, not local time, and this is confirmation of our hypothesis. The curves to which reference has been made are derived<sup>2</sup> from the observations of potential gradient over the oceans; the curve used for comparison with the Kew potential gradient on summer depends on observations during the months May to October, and that for comparison with the Kew gradient in winter on observations during the

<sup>2</sup> Whipple, *Q.J.R. Met. Soc.*, 1929, 55, 9.

months November to April but the difference in type is slight, so that no serious error can be introduced by this selection of months.

The curves indicate that the potential of the K.-H. layer is lowest about 4 h. G.M.T., and highest about 19 h. G.M.T. As was first noticed by Appleton, this is consistent with the ideas that the potential is maintained by the action of thunderstorms, that in any place on land thunderstorms are most likely in the late afternoon, and that the most thundery regions are in Africa and South America.

The next step is to consider the observations of the air-earth current at Kew. As will be seen from the curves in Figs. 1 and 2, the types of variation of the current in summer and winter are very different. In summer the current behaves in much the same way as the potential gradient at the same station, in winter there is a reversal.

Regarding the current as produced by the potential of the K.-H. layer, we investigate the changes in the resistance of a vertical column by dividing the potential by the current. We learn in this way that the resistance is least in the early morning, and increases fairly steadily through the day, the maximum being reached about 18 h.

The specific resistance of the air in contact with the ground is found in the same way by comparing the potential gradient at Kew with the air-earth current. The specific resistance has two maxima and two minima in the twenty-four hours.

Thus it appears that the morning minimum and the evening maximum of potential gradient at Kew are due in part to the corresponding extremes of the potential of the K.-H. layer, but the morning maximum and the evening minimum are due entirely to local conditions.

At the time of the morning maximum of potential gradient the specific resistance near the ground is high, whilst the total resistance is low (in summer) or moderate (in winter). At the time of the afternoon minimum of potential gradient the specific resistance is moderate, whilst the total resistance is above the mean for the day. To explain the variations in the total resistance, we notice that the conductivity of the air depends on the number of small ions which it contains. The number of small ions depends on the rate at which ions are produced, and on the rate at which the lives of the small ions are terminated by their combination with nuclei, charged and uncharged. We do not know whether the rate of production fluctuates through the day at moderate heights in the atmosphere, but we do know that the number of nuclei will increase owing to the way they are steadily produced by fires and by the use of gas. According to the work<sup>3</sup> of Coste and Wright, nuclei are mostly nitrous acid  $\text{HNO}_2$  formed by the combination of the atmospheric gases nitrogen, oxygen and water vapour and therefore nuclei can hardly be regarded as pollution. They are produced, however, at the same time as the sooty particles which are pre-eminently pollution. The way in which the total resistance changes indicates that over a London suburb the number of nuclei increases steadily from the time when fires are lit in the morning until about 18 h. in the evening, and that the air clears gradually during the night. It is probable that at night in summer the nuclei are mostly sea-salt, as they are at all times over the oceans.

The double oscillation in the specific resistance of the air near the ground has been explained by Simpson. There is a rapid increase in the

<sup>3</sup> *Phil. Mag.*, 1935, 7, 20, 209.

resistance in the morning, but this increase is interrupted when the sun is up and the warming of the ground produces convection currents which carry pollution and nuclei upwards and allow purer air to descend. Convection becomes less vigorous in the late afternoon, and pollution increases to reach a maximum in the evening when domestic fires and domestic cooking-stoves are still active. The evening maximum is a little later in winter than in summer.

In this discussion we have dealt only with the proportional variation of the elements concerned. In considering the mean values, we are handicapped by not knowing at all precisely the mean value of the potential of the Heaviside layer at different seasons. There is reason to believe that the potential is higher in the northern winter than in the northern summer, for it is found both in the Arctic and in the Antarctic that potential gradient is higher in the former season, and the same relation has been observed over the oceans. On the other hand Mauchly's final analysis<sup>4</sup> of the Carnegie observations of potential gradient indicates no appreciable annual variation over the oceans. Balloon observations of potential gradient lead to an estimate of about  $2.5 \times 10^5$  volts for potential at 10 km. Above that level the gradient is very small. We take  $3 \times 10^5$  volts for the potential of the Heaviside layer at all seasons.

The best estimate of the air-earth current over the oceans can be obtained from the mean potential gradient and the conductivity due to position ions and is

$$1.3 \times 1.8 \times 10^{-16} = 2.3 \times 10^{-16} \text{ amp./cm}^2.$$

The following Table is completed<sup>5</sup> by taking Scrase's estimates of the potential gradient and air-earth current at Kew.

MEAN VALUES.

	Oceans.	Kew Observatory.	
		Summer.	Winter.
Potential of the Heaviside layer	3	3	$3 \times 10^5$ volts.
Potential gradient . . .	1.3	2.46	4.70 volt/cm.
Air-earth current . . .	2.3	1.48	$.74 \times 10^{-16}$ amp./cm. <sup>2</sup>
Effective resistance of air column	1.3	2.0	$4.0 \times 10^{11}$ ohm.cm. <sup>2</sup>
Specific resistance (+ ions) .	0.56	1.66	$6.35 \times 10^{10}$ ohm.cm.
Conductivity (+ ions) . . .	1.8	.60	$.16 \times 10^{-10}$ ohm. <sup>-1</sup> cm. <sup>-1</sup>
Conductivity in electrostatic units	1.6	.54	$.14 \times 10^{-4}$ sec. <sup>-1</sup>

It will be noticed that whereas the specific resistance at Kew is increased fourfold between summer and winter, the total resistance of the air-column is only doubled.

The minimum resistance, at 5 h., in winter, is nearly equal to the maximum resistance, at 18 h., in summer. Further, the winter maximum,

<sup>4</sup> *Carnegie Inst. Dep. Terr. Magn., Washington, 1926, 8, 403.*

<sup>5</sup> *Loc. cit.* Tables IV. and II. It is to be noted that an exposure factor has to be applied to the data in these Tables. The conductivity is derived here from seasonal means of current and potential gradient, whereas in Scrase's Table III. the values of conductivity for the months were averaged.

at 19 h., is about  $6 \times 10^{21}$  ohm. cm.<sup>2</sup>, whereas the summer minimum, at 2 h., is only  $1.4 \times 10^{21}$  ohm. cm.<sup>2</sup>, almost the same as the resistance over the oceans. Here, again, we have a fourfold increase.

So far, we have been concerned with the variation of the effective resistance of an air column. This effective resistance is virtually defined by the equation

$$V = iR,$$

$V$  being the voltage at the top of the column, and  $i$  the air-earth current, and it is important to notice that  $R$  is not the same as  $r$ , the integral of the specific resistance at all heights. This integral is defined by

$$r = \int_0^h \frac{dz}{\lambda_1 + \lambda_2},$$

in which  $\lambda_1$  and  $\lambda_2$  are the conductivities due to positive and negative ions respectively, and  $h$  is the height of the column. That  $R$  and  $r$  are not the same, is on account of the "electrode effect." Owing to the fact that negative ions cannot pass upwards from the ground itself, the current at the surface is conveyed only by positive ions. At a moderate distance from the ground there is an excess of positive charge, and in addition to the conduction current there is a diffusion current carrying positive electricity upwards. Above the region in which the "electrode effect" is appreciable the potential gradient is related to the conductivity by the equation

$$\frac{\partial V}{\partial z} = \frac{i}{\lambda_1 + \lambda_2},$$

whereas at the surface

$$\frac{\partial V}{\partial z} = \frac{i}{\lambda_1}.$$

To allow for the transition, which must be gradual, we may adopt the hypothesis that at any height the gradient is given with sufficient accuracy by the formula

$$\frac{\partial V}{\partial z} = \frac{i}{\lambda_1 + \lambda_2} + ic \exp(-z/a),$$

$a$  being a constant and  $c$  the value of  $\lambda_2/[\lambda_1(\lambda_1 + \lambda_2)]$  near the ground. This formula, which reduces to the two preceding ones if  $z \rightarrow \infty$  and if  $z \rightarrow 0$  respectively, does not imply that the  $\lambda$ 's are constant. By integrating the last equation, we find that

$$R = r + ac.$$

By adopting a simplified theory concerning the nature of the electrode effect, I calculated that the value of  $a$  would be of the order 30 metres. In this calculation,<sup>6</sup> it was assumed that  $\lambda_1$  and  $\lambda_2$  were independent of height, and that the coefficient of eddy-diffusion was also constant. It is known, however, from experiments at Kew that at that station, at any rate in the middle of the day, the potential gradient is nearly the same at 10 metres and at the ground. If our method of approximation to the value of  $\frac{\partial V}{\partial z}$  is valid, then  $a$  must be considerably greater than 30 metres. Let us suppose that  $a = 100$  metres, then with the average

<sup>6</sup> *Terr. Mag.*, 1932, 37, 355.

summer values of the conductivities  $c$  is about  $0.7 \times 10^{18}$  ohm. cm., and  $ac = 0.7 \times 10^{20}$  ohm. cm. As  $R$  in the same season is about  $2 \times 10^{21}$  ohm. cm.,  $r$  is then about 3 per cent. less than  $R$ .

In winter there is generally less diffusion by eddy motion, and it may be surmised that  $a = 50$  metres. In this season the average value of  $c$  is about  $2.5 \times 10^{20}$  ohm. cm., so that, according to our surmise,  $ac = 1.25 \times 10^{20}$  ohm. cm. With  $R$  at the average winter value,  $4 \times 10^{21}$  ohm. cm.  $r$  is again 3 per cent. less than  $R$ .

As to diurnal variation of  $ac$ , it is to be noticed that when the air is stable at night,  $a$  is likely to be small as well as  $c$ , so that the product  $ac$  is small then; in the morning  $c$  increases before there is much convection; later in the day,  $c$  decreases and convection increases; there is therefore not much to guide us in deciding at what hour  $ac$  is likely to have its maximum value. It may be that  $ac$ , like  $R$ , increases through the daylight hours. There is no reason to suppose that the difference between  $R$  and  $r$  is at any time much greater than the 3 per cent. which has been estimated as the average proportion, but it may well be that the difference can reach, say, 10 per cent. In that case, a considerable part of the regular diurnal change of  $R$  must be ascribed to the varying vertical extent of the electrode effect. In using the generalisation which has been put forward, that the resistance of the atmosphere increases throughout the hours when pollution is occurring, it must be borne in mind that the generalisation refers to the effective resistance  $R$ , and not to the true electrical resistance  $r$ . Whether  $r$  really behaves in the same way must be left undetermined.

This discussion is, it must be admitted, rather inconclusive. It may serve, however, to draw the attention of physicists to the difficulty of interpreting such simple observations as those of potential gradient. Systematic observations of what was then called electric tension were commenced at Kew Observatory in 1843. We are still a long way from fully understanding their significance.

*Kew Observatory.*

## ON SULPHURIC ACID MIST.

BY A. DOOLEY AND C. F. GOODEVE.

*Received 2nd April, 1936.*

Sulphur trioxide vapour, when passed in an air stream through water, is not appreciably absorbed, but is converted into a mist which is stable to acids and alkalis. On the other hand, when the vapour is passed through 98 per cent. sulphuric acid, it is practically completely absorbed. A number of theories have been suggested to explain this behaviour; for example, Sackur<sup>1</sup> thought that the sulphur trioxide was converted into an insoluble form,  $S_2O_6$ .<sup>2</sup> A more acceptable explanation was put forward by Walker, Lewis and McAdams,<sup>3</sup> who state that:

<sup>1</sup> O. Sackur, *Z. Elektrochem.*, 1902, 8, 77.

<sup>2</sup> I. E. Adadurov and D. V. Gernet, *J. Chem. Ind. Russ.*, 1931, 8, No. 18, p. 12, hold somewhat similar ideas.

<sup>3</sup> W. H. Walker, W. K. Lewis and W. H. McAdams, *Principles of Chemical Engineering*, 1923, p. 42.

"If one attempts to dissolve the trioxide in water or dilute sulphuric acid, the trioxide vapour first comes in contact not with the liquid but with the water vapour which has evaporated from the liquid into the gas. It reacts with this vapour, producing minute droplets of sulphuric acid in the form of a fog, and these droplets are effectively insulated from the absorbing liquid by the gas film. One must therefore use as an absorbent (for the trioxide) <sup>4</sup> a liquid, the water vapour pressure of which is negligible, i.e., strong sulphuric acid. This is the reason why for absorption one must use acid between 97 and 98 per cent. If more dilute, the pressure of water vapour is sufficient to produce a fog, if more concentrated the partial pressure of SO<sub>3</sub> over it is great enough to prevent complete absorption."

Recent experimental evidence strongly supports this latter explanation, and makes it possible to account more fully for the formation of sulphuric acid mist, and its various properties. In the first part of this paper, the whole mechanism is discussed, and in the second, the equilibria that obtain under various conditions have been calculated.

In problems dealing with sulphuric acid, it is very important to distinguish, as has been done by Miles,<sup>5</sup> between the absorption of sulphur trioxide vapour and the removal of sulphuric acid mist. These problems are quite separate, and their solutions generally lie in different directions.

### The Formation of Sulphuric Acid Mist.

Goodeve, Eastman and Dooley<sup>6</sup> have recently studied the kinetics of the reaction between sulphur trioxide and water vapours. It was found that the primary reaction

was approximately stoichiometric and very fast. Under the conditions described (i.e., at low pressures of reactants and a carrier gas pressure of about 5 mm.) about 1 collision in 100 between reacting gas molecules was found to be effective. This velocity corresponded approximately to the rate of termolecular collisions. It would probably, therefore, increase as the first power of the concentration of each of the reactants and of the pressure of the carrier gas. The fact that the reaction was not altered by careful purification of the gas to remove all particles of dust, led to the conclusion that the reaction was mainly homogeneous. These characteristics of the reaction resulted in a very narrow reaction zone, whose position was determined by the relative concentrations of the reactants and the diffusion velocities. The stoichiometric character of the reaction required that the rate of arrival of each of the reactants in the reaction zone should be the same, and, if the concentration or flow rate were altered, the zone would change its position until these conditions were fulfilled.\*

The rate of arrival of water vapour at the reaction zone is a function of the concentration gradient which, in turn, depends on the rate of evaporation of water from a liquid surface. This latter problem has

<sup>4</sup> The words in brackets are the authors.

<sup>5</sup> F. D. Miles, *Manufacture of Sulphuric Acid (Contact Process)*, 1925, p. 209.

<sup>6</sup> C. F. Goodeve, A. S. Eastman and A. Dooley, *Trans. Faraday Soc.*, 1934, 30, p. 1127.

\* See Fig. 2, previous paper.

been studied recently by Alty and co-workers,<sup>7</sup> who find that the rate of evaporation is approximately one-thirtieth of the rate of surface collisions for the saturated vapour. On the other hand, they find that the accommodation coefficient for transfer of energy of collisions of water molecules with a water surface, is unity. The accuracy of their experiments was not high, owing to necessary extrapolations, and it would appear that the value ( $\alpha_0^1$ ) for their first coefficient represents a minimum. The rate of evaporation of water into a vapour whose pressure is 1 mm. below the equilibrium pressure can, therefore, be calculated to be at least  $2 \times 10^{19}$  molecules per second per sq. cm. Unless the rate of arrival of sulphur trioxide is greater than this, the water surface will always be protected by a layer of water vapour.

This forms a starting point for the development of a three-stage mechanism of mist formation. The high velocity of the reaction producing molecular hydrogen sulphate does not permit the sulphur trioxide, as such, to reach the water surface. This hydrogen sulphate will be in a state of supersaturation and its concentration will increase until it reaches a critical value, whereupon condensation will occur with the production of agglomerates or nuclei of hydrogen sulphate. This is the second stage. The delay which occurs in reaching this critical point gives rise to the periodic phenomenon described in the previous paper. A few molecules of hydrogen sulphate will, however, penetrate the protecting water layer and enter the liquid water. The number that do this will depend chiefly on the distance between the reaction zone and the water surface.

The concept of the formation of nuclei of an involatile material as a necessary preliminary to the formation of a mist has been advanced by Townsend,<sup>8</sup> and supported by Rothmund<sup>9</sup> with regard to mists of sulphuric acid and iodic acid, and by Philip and co-workers<sup>10, 11</sup> with respect to mists of hydrogen chloride.

The average number of molecules in these nuclei depends upon a number of conditions as yet not fully understood. This number may depend on the rate of condensation as normally controlled by the partial pressures, the number of foreign nuclei such as dust or ions, the rate of cooling of the carrier gas,<sup>12</sup> etc. Some important factors affecting its value are discussed by Freundlich.<sup>13</sup> In addition, a theory based on initial aggregation of molecules has been proposed by Volmer.<sup>14</sup> A theory of this type is favoured here, as it gives a simpler explanation of the delay in precipitation found in the periodic phenomenon. The size of the nuclei is of major importance in determining the equilibrium conditions of the mist, as will be discussed below.

The third and final stage in the process occurs when the agglomerates of hydrogen sulphate are carried by the air stream into a part containing excess of one or other of the reactants. This is absorbed until equilibrium is attained, resulting in the production of particles of strong light-scattering power which form the well-known sulphuric acid mist.

<sup>14</sup> M. Volmer, *Z. Elektrochem.*, 1929, 35, 555.

The two types of mist described by Remy,<sup>15</sup> and called "wet" and "dry" mists, correspond to the cases where the hydrogen sulphate nuclei pass into an atmosphere containing excess water vapour and excess sulphur trioxide, respectively. "Wet" mist consists, therefore, of droplets of sulphuric acid in various stages of dilution, and the "dry" mist, of droplets of oleum. Although these two mists are different as regards composition and some properties, their modes of formation are strictly analogous. For example, the periodic phenomena could be produced in an identical manner simply by reversing the relative concentrations of reactants.

The above mechanism has been demonstrated by a simple experiment in which air-sulphur trioxide mixtures were passed into a tube in which was placed a drop of water, as shown in Fig. 1. The clear space between the reaction zone and the liquid water was readily visible, as was also the carrying

Fig. 1.

away in a thin layer of the sulphuric acid mist from the water. The drop was found to evaporate rapidly. Generally, however, the drop did not evaporate completely as some sulphuric acid diffused through to the water, was dissolved and lowered the vapour pressure of the water. This lowering resulted in an approach of the reaction zone and a still greater penetration of the sulphuric acid. Eventually, the whole system ceased to produce mists in the tube.

As was to be expected, the same phenomenon could be demonstrated by having water vapour in the air stream and a drop of strong oleum (about 50 per cent. free SO<sub>3</sub>) in the tube.

The efficiency of removal of *sulphur trioxide* from an air stream is, according to the above mechanism, almost entirely dependent on the lowness of the vapour pressure with respect to SO<sub>3</sub> or H<sub>2</sub>O. The importance of low partial vapour pressures of the absorbing medium has often been emphasised. Miles<sup>16</sup> has shown by a series of experiments that the efficiency of absorption increases very rapidly with decrease of temperature. In the design of commercial plant, special precautions are taken, as described by Fairlie,<sup>17</sup> to ensure that the final absorption is done with cold acid.

Presumably a solution of any non-volatile substance which will reduce the vapour pressure of water to a very low value could be used as an absorbing medium—that is, the power of absorption may not be specific to sulphuric acid.

### The Stability of Sulphuric Acid Mist.

The stability of mists to alkalis, etc., has at times been attributed to adsorbed air films, electrical charges, etc.<sup>18</sup> The existence of strongly adsorbed air films at liquid surfaces has not been proved, and is not to be expected, the low solubility of air in liquids indicating a low attraction between air molecules and liquids. Air cushions between colliding droplets of reasonable size are well known, but their effect in preventing contact on collision decreases very rapidly with decrease in droplet size.

<sup>15</sup> H. Remy, *Z. Elektrochem.*, 1922, **28**, 467.

<sup>16</sup> F. D. Miles, *loc. cit.*, p. 250.

<sup>17</sup> A. M. Fairlie, *Sulphuric Acid Manufacture*, 1936.

<sup>18</sup> See W. E. Gibbs, *Clouds and Smokes*, 1924, p. 96.

A thermodynamic metastability of aerosols due to adsorbed electric charges of one sign, as occurs with ordinary liquid colloids, is not possible in a medium of very low dielectric constant. In addition, Remy and Koch<sup>19</sup> found that mist particles of sulphuric acid were uncharged.

The whole subject of the stability of aerosols has been made clear by the work of Tuovila and of Whytlaw-Gray and collaborators.<sup>20</sup> It has been found for stearic acid that every collision between mist particles results in their coalescence, and that the so-called stability can be entirely accounted for by the low diffusion velocity and low collision frequency of the particles. This indicates that adsorbed air films and electric charges, if present, were without effect.

Although no quantitative experiments have been performed for sulphuric acid mist, there is no reason to doubt that the same conditions apply, and therefore we can assume that the "resistance" of sulphuric acid mist to scrubbing agents is simply an indication of the low diffusion velocity.

### Equilibrium Conditions for Sulphuric Acid Mist.

Although the stability of mists with time is only an apparent one, the particles themselves come into true thermodynamic equilibrium with the reactant vapour which happens to be in excess. The case in which water vapour is in excess is considered in the following. It is possible to obtain an equilibrium even when the partial pressure of water is equal to that over a pure water surface. Townsend<sup>8</sup> derived an expression for the radius of a droplet in a water-saturated atmosphere, in terms of the osmotic pressure "of the soluble body." He equated the increase in vapour pressure due to curvature, as given by the Kelvin equation, to the lowering of vapour pressure of water corresponding to the osmotic pressure. Rothmund<sup>9</sup> obtained a similar expression,<sup>21</sup> using Raoult's law and the Van t'Hoff factor  $i$ . For an iodic acid mist, he found agreement between values for the radius so obtained, and as calculated from the rate of fall using the Stokes-Cunningham relationship. These equations can only be used for large particles where the approximations are valid, and for droplets in equilibrium with saturated water vapour. Under conditions other than these, as is shown below, the equilibrium radius is practically independent of concentration, except for droplets containing a given number of sulphuric acid molecules.

In order to follow the increase or decrease of size of a mist particle resulting from a change in the vapour pressure, it is necessary to proceed in another way. For a given droplet, the one important quantity which does not vary is the content of hydrogen sulphate, *i.e.*, the size of the initial nucleus. This may, however, vary considerably for droplets formed under various conditions. The variables concerned are inter-dependent, and this inter-dependence is not of a simple form. It is not useful to attempt a single equation to express the conditions obtaining in sulphuric acid mist. It is, however, possible to construct a series of curves showing the growth of droplets of sulphuric acid mist derived from

<sup>19</sup> H. Remy and C. Koch, *Z. anorg. Chem.*, 1924, 139, 69.

<sup>20</sup> This question has been fully discussed in *Smoke* (1932), by Whytlaw-Gray and Patterson.

<sup>21</sup> Care should be observed in using Rothmund's equations, as he has omitted the density in two of them. His last equation is correct as the density would have cancelled out.

hydrogen sulphate nuclei of various sizes in the presence of water vapour at various pressures.

The Kelvin equation for variation of vapour pressure with curvature is derived thermodynamically<sup>22</sup> in, for example, Guggenheim's *Modern Thermodynamics*.<sup>23</sup> This equation may be written—

$$RT \log_e \frac{P}{P_0} = \frac{2\gamma}{r} \frac{dv}{dn} \quad (1)$$

where  $R$  is the gas constant,  $T$  the absolute temperature,  $P$  and  $P_0$  the vapour pressures over the droplet and corresponding plane surface respectively for the same strength of solution,  $\gamma$  the surface tension,  $\frac{dv}{dn}$  the partial molar volume and  $r$  the radius. The quantities  $P_0$ ,  $\gamma$  and  $\frac{dv}{dn}$  are all functions of concentration, and these functions can only be expressed in the form of experimentally determined curves. These have been drawn in Fig. 2, the temperature throughout being 20°C. The

Fig 2 Physical Properties of Sulphuric Acid as used in equation 1

values of  $P_0$  were taken from the International Critical Tables,<sup>24</sup> of  $\gamma$  from the results of Linebarger<sup>25</sup> (corrected for the now accepted value for water), and of  $\frac{dv}{dn}$  from the specific volume-concentration curve by the method of intercepts.<sup>26</sup> In obtaining Fig. 2, the values of the concentration in grams  $H_2SO_4$  per c.c., were first plotted against  $\log_{10} \frac{r}{r_0}$  (where  $r_0$  is the radius of the initial nucleus of hydrogen sulphate), a purely geometrical calculation. Values of the

other variables were then plotted through this concentration on the  $\log_{10} \frac{r_0}{r}$  scale. All of the essential data are shown in this figure.

The quantities  $\gamma$  and  $\frac{dv}{dn}$  are also functions of the radius. The amount of the correction for change of surface tension with curvature has apparently not been calculated, but would be of minor importance at diameters above  $10^{-6}$  cm.—that is, where the curvature is small compared with that of the molecules. The correction for variation of partial

<sup>22</sup> A number of kinetic derivations have also been made. For example, see S. W. Gorbatschew, *Kolloid Z.*, 1935, 73, 263.

<sup>23</sup> E. A. Guggenheim, *Modern Thermodynamics*, 1933, p. 170.

<sup>24</sup> Vol. III., p. 302.

<sup>25</sup> C. E. Linebarger, *J.A.C.S.*, 1900, 22, 5.

<sup>26</sup> Lewis and Randall, *Thermodynamics*, p. 38.

molar volume with curvature<sup>27</sup> is also very small, and most likely much less important than the change of surface tension. These corrections will be neglected here as we are generally dealing with droplets of sufficient size to give a strong Tyndall beam—*i.e.*, greater than  $10^{-6}$  cm. The effect of electrical charges is also not considered.<sup>28</sup>

Values for the equilibrium pressure  $P$ , over droplets of radius  $r$ , arising out of an initial nucleus of hydrogen sulphate of radius  $r_0$ , have been calculated for a series of selected values of the latter, using Equation (1). The resultant members of a family of curves are shown in Fig. 3, the equilibrium vapour pressure being plotted against the logarithm of the droplet radius. The curves trace the history of the growth of the sulphuric acid droplets, excluding coagulation by collision, and show the equilibrium size to be expected when the droplets are carried in a gas containing water vapour at various partial pressures. When air carrying droplets of sulphuric acid mist is passed through liquid water, it becomes

Fig. 3 The Growth of Sulphuric Acid Mist Droplets from Hydrogen Sulphate Nuclei of Radius  $r_0$

saturated with water vapour to a partial pressure, as indicated by the horizontal broken line. Water vapour will condense on the mist particles until their radius is raised to the value given by the point where the curve crosses this horizontal line. The parts of the curves above this line represent an unstable state, and the droplets will lose water until they reach the equilibrium radius. The rate of evaporation of water from such droplets will be a function of the distance from the

<sup>27</sup> Kritschevski, *Kolloid Z.*, 1934, 68, 15, has calculated a correction for change of volume with curvature, based upon an equation taken from Lewis and Randall (*loc. cit.*, p. 252). However, he has apparently confused partial molar volume and total volume. At all events, the equation given by Lewis and Randall cannot be accepted if for no other reason than the fact that it is derived from the variation of free energy for a change in a system which cannot possibly be considered as reversible.

<sup>28</sup> The effect of charges has been calculated by J. J. Thomson, *Conduction of Electricity through Gases*, 1928, Vol. I., p. 325 *et seq.*

appropriate point on the curve to the horizontal line, and will pass through a maximum as a large drop evaporates.

A similar set of curves may be plotted for the case of  $\text{H}_2\text{SO}_4$  nuclei in an atmosphere containing gaseous  $\text{SO}_2$ . The vapour pressure of  $\text{SO}_2$  over the various strengths of oleum would then be represented by  $P_0$ , and the other physical properties of this material would be used where required. These curves would be useful in considering the general properties of oleum mists.

A comparison of Fig. 3 with Fig. 2 will show that the variation of vapour pressure with concentration is the major factor in determining the equilibrium pressure of the drop. The concentration does not depend markedly upon radius for a given partial pressure, and a determination of concentration cannot readily be used to determine the size of the droplets. A heterogeneous mist containing particles whose sizes are spread over a wide range will give effectively the same value for concentration as a homogeneous mist, so long as none of the droplets are below  $10^{-6}$  cms. A number of experiments in which the mist was carefully collected and analysed and the water partial pressure measured, were carried out, and were in conformity with these conclusions.

For all of the curves shown in the figure, there is a definite point of intersection with the saturated vapour pressure line, but the angle of intersection and the height of the maximum decrease very rapidly with increase in initial hydrogen sulphate content. This maximum has no special significance beyond showing the amount of super-saturation which it is necessary to obtain in a gas before the particles can grow indefinitely. A pressure line corresponding to a supersaturation below the maximum (such as the line SS, Fig. 3) will cut a curve in two positions; only one of these, A, however, represents a stable system. This is the one corresponding to the smaller radius. A droplet whose conditions correspond to the point of intersection, B, would have the same vapour pressure as the surroundings, but, if an infinitesimal amount of water is added to, or subtracted from the droplet, it will immediately become unstable, and will either increase to infinity or decrease to the radius of the point, A. The point B represents a type of false equilibrium, and droplets at this point are in an unusual position in so far as the addition of water *reduces* their water vapour pressure and *vice versa*.

A number of interesting conclusions concerning the removal of sulphuric acid mist can be drawn from these results. Mist particles can be removed either by reducing their size so that their Brownian movement becomes very high, or increasing their size so that they settle out by gravity or can be thrown out by centrifugal force. Sufficiently small particles cannot be obtained merely by drying if the initial nucleus is greater than about  $5 \times 10^{-7}$  cms. radius, and below this size the vapour pressure of the medium does not make a very great difference to the Brownian movement of the droplets. It is more usual to remove sulphuric acid mist by settling or by centrifugal means.<sup>29</sup> A first requirement in obtaining large particles is to start with large hydrogen sulphate nuclei; the degree of supersaturation required being smaller, the larger the nucleus. Subject to the considerations given in a following paragraph, the particles can then grow to infinite size with a very small degree of supersaturation.

The curves explain the results of Remy,<sup>18</sup> who found that pure water

<sup>29</sup> See paper by one of the authors (C. F. G.), this volume, p. 1218.

absorbed *sulphuric acid mist* much better than did concentrated sulphuric acid. A casual examination leads one to the reverse conclusion, as the intensity of a mist is always increased by passing through water, whereas it is decreased on passing through sulphuric acid. This is due, of course, to a very large change of particle size.

The absorption of mist by water has been demonstrated in the course of this research in a simple way. A long horizontal tube was half filled with water, and a stream of air containing sulphur trioxide passed in one end. The growth of mist particles along the tube was readily visible, and at low flow rates they fell to the water surface completely before reaching the end of the tube. With 30 per cent. sulphuric acid, on the other hand, no such growth or falling of the particles was observed.

These experiments illustrate the contrast between the absorbing media most suited for the removal of sulphur trioxide and sulphuric acid mist, respectively. For the former, extremely low water vapour pressure is essential, whereas for the latter saturated or supersaturated water vapour pressure is more effective. The overall efficiency of a washing tower will pass through a minimum as the absorbent liquid is changed continuously from 98 per cent.  $\text{H}_2\text{SO}_4$  to pure water.

It remains to consider how long it will take for equilibrium to be established when the conditions of the carrier gas are changed. The rate of evaporation and condensation of water vapour from pure water has been determined experimentally by Alty and co-workers,<sup>7</sup> and it is probable that for sulphuric acid the rate will be the same when multiplied by the relative vapour pressures. Very approximate calculations from their results indicate that in one second after changing the conditions of the carrier gas, equilibrium within a few per cent. will be re-established. Probably the most serious cause of lag in the establishment of equilibrium will be the change of temperature of the droplets due to the condensation or evaporation of the vapour. A theoretical treatment of this has recently been made by Fuchs.<sup>30</sup> Townsend<sup>8</sup> showed that iodic acid mists could be rendered invisible merely by a passage through concentrated sulphuric acid, but that, on replacement of the water by subsequent bubbling through the latter, the original intensity of visible mist was obtained. Such experiments have been repeated with sulphuric acid mist in the present work, and it was found that strong drying agents, such as phosphorus pentoxide and concentrated sulphuric acid, readily reduced the size of the particles until they became invisible, and on passing over water, the mist again grew to its original density. These experiments were carried out in a long tube and the rate of increase of the size of the particles could be easily seen. The experiments were purely qualitative, but sufficed to show that equilibrium was re-established in a few seconds.

### Other Mists.

Any volatile anhydride which reacts extremely rapidly and practically irreversibly with water vapour, producing a non-volatile substance, will almost certainly be only partially absorbed when passed in an air stream through water. Acetic anhydride, chlorine heptoxide and nitrogen pentoxide are additional examples of substances which act in this way.

<sup>30</sup> N. Fuchs, *Physikal. Z. Sowjetunion*, 1934, 6, 224.

In all these cases it is likely that the mechanism is the same as that described for sulphur trioxide in the first part of this paper.

It would also be instructive to draw vapour pressure-radius curves for mists arising from the anhydrides mentioned in the preceding paragraph. These curves would be similar to those in Fig. 3. As far as is known, the mists behave in the same way. Mists formed by the hydrogen halides with water (generally in the presence of foreign nuclei) belong to a more complex but especially interesting group. In these cases, both vapours are present in the gas phase. If the partial pressure of one of these vapours is taken as constant, curves representing the change in partial pressure of the other with radius could be plotted for droplets arising out of non-volatile nuclei of various sizes. These would be somewhat similar to those in Fig. 3. In the absence of nuclei, the curves would not fall below the equilibrium pressures for flat surfaces, and therefore no mist particles could be obtained except at high supersaturations. This is in agreement with the results of Aldis and Philip.<sup>10</sup> Askew<sup>21</sup> found that mist formed more readily with hydrogen bromide than with the chloride. This follows from the much lower partial vapour pressure of the bromide over its aqueous solutions.<sup>22</sup> It may be that the discrepancy between the calculated and observed sizes of hydrochloric acid mist droplets found by Jackson and Philip<sup>11</sup> would be removed if consideration were given to the above points.

### Summary.

Recent measurements of the velocity of the reaction between sulphur trioxide and water vapours and the phenomena accompanying the production of sulphuric acid mist, are shown to support the explanation of Walker, Lewis and McAdams for the non-absorption of sulphur trioxide in water and its absorption in concentrated sulphuric acid. It is also shown that the size of the initial hydrogen sulphate nucleus is the important factor governing the change in droplet size with the change in the water vapour pressure of the medium. Curves have been drawn showing the growth of mist particles under various conditions, and their technical importance discussed. It is suggested that these considerations can be applied to other mists.

## THE REMOVAL OF MIST BY CENTRIFUGAL METHODS.

By C. F. GOODEVE.

The problem of removing droplets of oil or other liquids from air has been recognised as a difficult one. Very small drops (radius less than  $10^{-6}$  cms.) with high Brownian motion are easily removed with filters, as they collide readily with the walls. Large drops (radius greater than  $10^{-4}$  cms.) have a negligible Brownian motion, but may be taken out

easily by centrifugal separation. The removal of droplets of sizes in the intermediate range has not been completely accomplished, except by electrostatic precipitation methods. In this paper, centrifugal methods developed in the course of work on mists of various types are described.

### Impinging Gas Stream Methods.

The method for the detection and removal of mist droplets, in which the air stream is caused to impinge as a fine jet against a clean glass plate, has been applied by many experimenters with considerable success. The

FIG. 1.—Cross-section of separator unit for the removal of mist droplets. E—Entry. D—Distance lugs. P—Collecting plate. W—Adjusting washers. C—Wall of container.

action depends on the centrifugal force on the particles during the rapid change in direction. This type of apparatus was modified by Calder and Fox<sup>1</sup> for use in the technical removal of sulphuric acid mist. In their original design, they used a large number of holes in plates arranged in series. They have improved their apparatus from time to time, and, in particular, they have found it more useful to apply a very high centrifugal force for a short period rather than a lesser force for a longer period.

The apparatus of Calder and Fox has the disadvantage that relatively wide jets have to be used to prevent stoppage and to give a reasonable capacity to the apparatus. These wide jets cause a reduced efficiency.

<sup>1</sup> Calder and Fox, *B.P.*, 1916, 126,320; 1922, 206,229; 1923, 228,646; 1924, 240,224.

In the apparatus described below, this difficulty has been avoided by using a narrow annular jet which allows a high capacity with a very short distance for the droplets to move transversely through the airstream. This apparatus has been used for some years on a technical scale to remove the mist droplets in the compressed air supplies (5 lbs. per sq. in.) of this laboratory and a number of others.

The final design of the apparatus, as prepared and made by Messrs. Reavell & Co., Ltd., Ipswich, is shown in the figure. The annular jet is  $\frac{3}{8}$  in. wide and 12.4 ins. in circumference. Most of the pressure drop (generally 2 lbs. per sq. in.) takes place in the jet, producing a linear velocity of 370 ft. per sec. at the orifice. The air impinges against a collecting plate fitted close to the jet. The flow of the air is split into two parts, moving in opposite directions and at right-angles to the original flow, while the mist droplets carry on until they strike the collecting plate. The maximum thickness of air through which the droplets must pass is  $\frac{1}{16}$  in. The air returns through the centre of the jet and along the outside, while the collected liquid falls through openings from the plate. The capacity of this separator unit for a 2 lb.-pressure drop is 30 cubic ft. free air per min. Generally two or three of these are used *in parallel* and are connected directly to the compressor.

Tests have been made on the content of oil droplets in the compressed air supply (arising from the high-speed rotary compressor) from time to time during the past three years. The separator units have been found to remove all oil droplets large enough to settle out and produce oil films in glassware and apparatuses commonly used with compressed air in the laboratory. Occasionally, however, it has been found possible to detect traces of oil by the jet and glass plate method referred to above. The units have not been found to remove completely the dust generally found in London's atmosphere. The efficiency may be increased by using a higher pressure drop and a smaller jet. The dimensions given, however, are convenient for general purposes.

The units have been examined every year and only a very small amount of grit has been found to collect in the annular jet. They have not been found so efficient for the removal of oil droplets in high-pressure air, owing, presumably, to the higher density of the medium through which the droplets must pass and to the greater turbulent motion produced at the jet. It may be possible to modify the design by the application of hydrodynamical principles to produce a device suitable for this purpose.

## Filters.

The action of filters in removing mist droplets is mainly centrifugal<sup>1</sup>—droplets much smaller than the sizes of the pores being readily removed. A very simple and efficient filter has been formed from a layer of glass or silica powder on coarse sand. The finest grade of Jena sintered glass filters, No. 4, has an equally high efficiency and is very convenient to use. The pore size of this filter has been estimated by the makers<sup>2</sup> to be  $2$  to  $5 \times 10^{-4}$  cm.

These filters have been tested with various mists. For example, sulphuric acid mist has been made under controlled conditions and tested before and after passing through the Jena filter, with a Tyndall beam from a Pointolite lamp. The size of the mist droplets was reduced continuously by lowering the partial pressure of the reactants until the blue mist just disappeared. It is estimated that the size of the droplets before the mist disappeared was  $10^{-4}$  cms. In all cases no trace of a Tyndall beam could be seen in the air which had passed through the filter. Similar tests were made with hot exit flue gases from a power station boiler, with the same

<sup>1</sup> W. E. Gibbs, *Clouds and Smoke*, 1924, p. 88.

<sup>2</sup> See J. W. McBain and C. R. Dawson, *Proc. Roy. Soc.*, 1935, 148A, p. 32.

result. Some filters have, however, been found to pass a certain amount of dust from the atmosphere, as detected by the single jet described above. Particularly is this the case when the filters were new and dry, but their efficiency always increased when used.

Although no evidence has been obtained to show the removal of droplets whose size is below that necessary to give a Tyndall beam, it is unlikely that such droplets pass through the filter. Freundlich<sup>4</sup> has shown that, with a coarser filter, the optimum transmission occurs for droplets of  $10^{-4}$  cms., and that droplets below this size are readily trapped by their Brownian motion.

These filters have often been used for determining the amount of sulphuric acid present in London's atmosphere in the presence and absence of fog. A high velocity of flow was obtained by connecting the filter to the suction side of a vacuum pump, the discharge side being connected to a gas meter. They have also been used to measure sulphuric acid mist in exit flue gases. They have the important advantage of being inert to acids and they are readily cleaned. They may find uses in other problems connected with the analysis of mists.

It is important to recognise that filters do not give the concentration of the mist droplets but only the total content of the non-volatile components.

*(Added in Proof.)*

### Removal of Fogs and Smoke by Falling Drops.

The interesting problem of the removal of smoke or fog particles by falling raindrops has been referred to by Dr. Dobson. A particle in the path of a falling drop will be caught, providing its inertia is sufficient to overcome the outward flow of air in front of the drop. It can readily be seen that the chance of a particle being so caught will be unity if it lies on the axis of the path, but will fall rapidly as its distance from the axis increases. The chance will also increase as the velocity of the falling drop is increased. The relation in this case is, however, rather complicated. Heavier particles will, of course, be trapped more easily than lighter ones.

A few experiments were made with an apparatus in which a drop of a definite size could be maintained on the end of a very fine capillary tube in an upward flowing air stream containing sulphuric acid mist. It was found possible to vary the size of the drop and the velocity of the air stream over quite wide limits. Measurable quantities of sulphuric acid were found in the drop after a short run but the effects of the variables referred to above were not studied.

### GENERAL DISCUSSION.\*

Dr. B. W. Bradford (*Billingham*) said: The curves given by the authors (Fig. 3) for the growth of sulphuric acid droplets refer rigidly only to aerosols at infinite dilution. In practice, aerosols of the concentrations usually encountered in any but meteorological work aggregate so rapidly that vapour-pressure equilibrium cannot be attained except in the final stages of growth, when the particle concentration has diminished to very low magnitudes.

\* On the two preceding papers.

Particle size determinations by several methods on a highly concentrated sulphuric acid mist (15 g./M<sup>3</sup>) produced by hydration of SO<sub>3</sub> in the presence of excess water vapour, gave concordant results, which agreed well with the rate of aggregation calculated from the Einstein-Smoluchowski formula. A particular search was made for inhomogeneities of droplet radius: it was found, however, that the variations were less than the experimental error of about 5 per cent.

In the practical determination of mist concentrations in saturated gases by methods involving a sudden pressure drop (*e.g.* filtration or impingement) it is important to note that the apparent mist concentration may be appreciably increased by condensation of vapour due to cooling by expansion at the orifice. This source of error is usually greater than that due to the fact that vapour pressure equilibrium in the aerosol refers to a highly curved surface while in the mist-sampling apparatus the surface on which the scrubbed mist collects is approximately plane.

**Professor H. Köhler** (*Uppsala*) said: How does Dr. Goodeve explain the condensation in a Wilson chamber, where the supersaturation is so great. Again, does the Aitken Nucleus Counter really give the number of nuclei; it is generally believed that the number of droplets formed, is the same as the number of nuclei.

**Mr. C. F. Goodeve** (*London*) (*communicated*): Clusters will be stabilised if given an electric charge, owing to the increased attraction to the polar water vapour molecules. Nuclei will, in general, facilitate condensation and, if present in sufficient numbers, prevent the attainment of the degree of supersaturation necessary for the growth of clusters to droplets. Under most conditions, therefore, the Aitken Nucleus Counter will probably give the correct result.

**Dr. N. Fuchs** (*Mcscow*) (*communicated*): To the three stages of formation of a sulphuric acid mist mentioned by Dooley and Goodeve, one more must be necessarily added, namely the coagulation of the growing nuclei and of the finally developed droplets. The rôle played by coagulation in the formation of the sulphuric acid mist can be seen, *e.g.*, from our experiments in which, by a quick mixing of two air-jets containing vapours of water and sulphur trioxide at partial pressures of about 1 mm., a primary mist was formed containing about 10<sup>11</sup> droplets per c.c. of 1.2 to 1.5 × 10<sup>-6</sup> cm. radius. Such a mist coagulates with a tremendous velocity, and in one second the number of particles per c.c. is reduced about a hundredfold, and the mass of the droplets accordingly increased.

**Mr. A. Dooley** (*Birmingham*) (*communicated*): It is incorrect to say that the Calder-Fox Scrubber is limited to "wide jets used to prevent stoppage and to give a reasonable capacity to the apparatus." In a modified form, now in general use, the scrubber is built up of glass strips arranged to give narrow slits behind which are supported further strips on edge. This design permits the adoption of the most suitable dimensions and clearances for any particular purpose. Units with 1/32-inch slits are in use on, for example, sulphuric acid concentrators but, if necessary, 1/64-inch slits could be arranged by using ground glass strips.

Blocking of the slits by solid matter depends on slit dimensions, and on the position and arrangement of the striking or "back" plate. In the Calder-Fox apparatus referred to above, overlap of the "back" strips is a minimum. No advantage in this direction could be claimed for Mr. Goodeve's apparatus.

While admiring the design of Goodeve's apparatus in so far as it is applied to the particular purpose stated, *viz.*, the removal of oil mist from 30 cubic feet of air per minute, I feel it necessary to point out that there would be serious limitations to its application to systems on which the Calder-Fox Scrubber is employed. On a technical scale gas volumes of upwards of 1000 cubic feet per minute are frequently handled, and it is evident that a circular form of apparatus would be unwieldy if in one unit or, if the necessary capacity were obtained by multiplication of

smaller units, unnecessarily complex. Furthermore, the question of materials of construction would require consideration if corrosive fumes were to be handled, and here also the Calder-Fox Scrubber appears to have the advantage.

**Dr. N. Fuchs (Moscow) (communicated):** The chief rôle in the removal of the droplets of  $10^{-5}$  cm. radius and less by means of porous and fibrous filters is played, not by the centrifugal forces, but by the Brownian movement of the droplets. This may be seen, *e.g.*, from the fact that such droplets pass the filter more easily the larger the linear velocity of flow through the filter. Centrifugal forces would evidently give the opposite relationship. The same conclusion may be reached theoretically by calculating the effect due to inertial forces by the method of Albrecht.<sup>1</sup>

It is difficult to estimate correctly the efficiency of the glass filters spoken of by Goodeve in respect to sulphuric acid mists, because he does not indicate the velocity of flow in his experiments. It is doubtful whether the finest mists in these experiments consisted of droplets as large as  $10^{-4}$  cm. As was shown in our laboratory,<sup>2</sup> no Tyndall beam can yet be observed in highly concentrated ( $10^9$  droplets per c.c.) sulphuric acid mists with droplets of even  $3 \times 10^{-5}$  cm. diameter (arc lamp illumination.)

**Mr. C. F. Goodeve (London), said:**

*In reply to Dr. Bradford and Dr. Fuchs:* The vapour of a droplet formed as a result of a collision between two droplets remains practically unchanged except when the droplets are below visible dimensions. This can be confirmed by a careful examination of Figs. 2 and 3. It is, of course, impossible to represent, in a single diagram, all variables which occur in practice.

*In reply to Dr. Bradford:* I have emphasised in my paper on centrifugal methods that it is impossible to determine a mist concentration (expressed either as number of droplets or grams, per unit volume) by any apparatus in which the droplets are removed. This arises from the fact that removal invariably alters the surface area and curvature. Centrifugal methods can only be used to determine the concentration of a non-volatile constituent of a mist and, of course, condensation of vapour due to cooling does not in any way enter.

*In reply to Mr. Dooley:* I agree that the modified form involving the use of glass strips is a considerable improvement over the previous type of apparatus. Unless wedge-shaped glass strips are used, however, there will be a very large loss of power in obtaining the linear high-speed flow desired for efficient removal.

## PART II.: THE INDUSTRIAL ASPECTS OF DISPERSE SYSTEMS IN AIR AND GASES. INTRODUCTORY PAPER.

By R. LESSING.

*Received 14th April, 1936.*

Disperse systems in gases in their relation to the problems of industry and the amenities of life have not yet received the close study which their ubiquity and practical importance demand. The present survey is therefore not intended to be a record of work done, but to indicate the problems which still await solution and the directions in which the results

of fundamental investigations can and should be applied in practice. The dispersoids to be considered comprise solids, liquids, solids covered with liquid films and liquid droplets containing solid nuclei.

Some of these systems happen to occur in many industrial operations, some form natural phenomena of climatic conditions, others are undesired concomitants of the atmosphere peculiar to civilised conditions of life and work, whilst yet others such as war gases and smoke screens, are set up intentionally as products of the latest developments of human activity.

### Dust.

The most common and quantitatively most important solid dispersoids are dusts. Systems containing these are probably also the simplest, and may therefore be considered first.

The most prolific source of dust production by man is grinding for size reduction, and this operation is carried out in the manufacture of flour, cement, fertilisers, coal, lime, chalk, gypsum, pigments, dyes, glass and pottery materials, rubber fillers, fish meal, potato meal and others. The total production of these materials in powder form approaches 20,000,000 tons per annum in this country.

All these industries comprise processes in which at some stage dust is dispersed in air. For reasons of economy, health and comfort, it is necessary to recover this dust and purify the air; hence, apparatus for dust collection is an essential component of their equipment.

Other types of dust, produced by abrasion, occur in the surface grinding, polishing and sandblasting industries. The quantities involved are of a much smaller order, but collection is not less difficult on account of the multiplicity of point sources of dust emission and their proximity to the respiratory organs of the workers.

Into this category falls the dust formation by drilling shot holes in mining and quarrying operations. In coal mining and handling, dust is raised in large quantities and high concentrations during blasting, loading and unloading, and particularly in screening. Some of this is formed by the disruptive action of explosives on the shale or sandstone and on the massive coal, and some is due to the dispersion of the more friable components of the coal seams. An intentional application of dust takes the form of "stone dusting" of underground roadways and working places for the prevention of coal dust explosions. There is at least one form of dust, *viz.*, road dust, that is rapidly diminishing, and has already disappeared from our principal highways, which are no longer constructed with waterbound, macadamised surfaces liable to severe attrition.

A problem affecting every individual is that of domestic dust and its collection after settlement by sweeping or by modern suction methods.

### Smoke.

True smokes, defined as dispersions in gases of solids formed by condensation and aggregation or coagulation occur in practice mainly in metallurgical operations in which metals or metallic oxides are volatilized by heat, either in bulk as in the "distillation" of zinc, or as the result of unavoidable side-reactions, as in most smelting operations. The recovery of valuable metals dispersed in waste gases as smokes is an important adjunct of modern metallurgy.

Common domestic "smoke" cannot strictly be grouped among the true smokes for reasons discussed below; the only true type of carbon smoke is the system formed by complete thermal decomposition of hydrocarbons or other volatile carbon compounds in which no liquid products are left.

### Fog.

Fogs are usually regarded as dispersions of liquids in gases, but it is questionable whether pure liquids are capable of fog formation without the aid of heterogeneous nuclei. Neither in meteorology nor in industry can systems be contemplated which are free from solid particles or substances soluble in the liquid dispersoid. Any definition of fogs as the formation by condensation of liquid droplets in the gas phase, must therefore comprise the presence or formation of dust or smoke particles, or of compounds soluble in the liquid phase. In practice, matters are complicated by the presence of a number of different kinds of particles or compounds, some of which are frequently unidentified and of unknown structure, composition and effect. The meteorological aspects of fog formation do not come within the scope of this paper, except as far as the supply of solid nuclei and of sulphur oxides from flue gas emission is concerned. The bulk of the chloride nuclei are, of course, derived from sea-water spray, but some hydrogen chloride is due to chloride in coal released upon its combustion.

An industrial fog of considerable technical importance is the tar fog in crude coal gas and coke oven gas. The tar droplets formed in the gas leaving the carbonising retorts or ovens by the rapid drop in temperature, give it the typical reddish-brown colour. I am not aware of any precise work on the structure of the droplets, their size distribution, and rate of coalescence, but there cannot be any doubt that the "free carbon" particles formed by the thermal decomposition of the primary decomposition products of coal, are the nuclei on which the liquid tar, together with water, or rather a solution of ammonium salts, condenses. The "free carbon" still contains several groups of asphaltic or bituminous substances.

The dispersoids of tar fog are therefore themselves a multiphase system; the principal phase is a complex mixture of hydrocarbons, oxygenated bodies, bases and pitch, and has a wide boiling range. They are dispersed in a gas phase containing, *inter alia*, the lower boiling hydrocarbons, which are solvents for the condensate. This system, which rapidly passes through a temperature gradient from 900° C. to 15° C., offers an interesting field of investigation. The persistence of some residual tar fog through the condensing system and the following gas purifying train, has recently led to the installation of electrical tar precipitators for the almost quantitative extraction of tar in fog form.

The formation of "gum" in coal gas is a phenomenon which has only recently become apparent since the adoption of the practice of eliminating naphthalene and some of the benzene hydrocarbons from the gas. The cause of "gumming" is not yet fully explained, but it is probably due to the action of nitrogen oxides on certain gas constituents; the reaction products are peculiar in coalescing from the dispersed state to tough masses when the gas passes through narrow orifices or channels.

In the manufacture of sulphuric acid, and particularly of oleum, the waste gases carry droplets of the acid in fog form. Presumably there are sufficient fine dust particles present, some of which are lifted from the

catalyst or catalyst carrier, which act as nuclei for the drop formation. This industry and the sulphide roasting industry were among the first to employ electrical precipitation for breaking up these very persistent acid fogs.

Oil fogs occur widely ; the most common form is that of the exhaust from motor engines, where solid nuclei are always provided by the " carbon " formed on incomplete combustion of the petrol air mixture. The oil fog from the lubricants of gas compressors is probably formed by a different mechanism. Decomposition at high temperatures does not take place and the cause must be sought in the stripping of the oil film on the cylinders at critical gas velocities.

The persistent fogs resulting from fatty acid distillation, rosin distillation or gum running must be classed as smokes, inasmuch as the dispersoids in the cooled system are more or less solid.

### The Flue Gas Problem.

The burning of fuels results in the creation of disperse systems in gases whose practical importance is only equalled by their theoretical interest and technical complexity. Even in the case of the combustion of gases—complicated enough *per se*, but relatively simple in comparison with that of solid fuels—disperse systems may be set up in the absence of a suitable excess of, or inadequate mixing with air, resulting in a smoky flame.

Liquid fuels in drop form are dispersed in air by spraying into the combustion chambers of furnaces or into the cylinders of internal combustion engines. The velocity and completeness of combustion depend, apart from the chemical and physical characteristics of the fuel itself, upon the subdivision and disposition of the liquid in the gaseous phase. The mechanism of " knock " during combustion under high compression has been studied intensively during recent years and the various theories advanced for it depend on the correct interpretation of the structure and behaviour of the disperse systems involved.

The combustion of coal provides a vast field for the study of disperse systems in gases. Quantitatively, its importance may be gauged from the fact that the portion of coal emitted from industrial and domestic chimneys constitutes the great bulk of the polluting matter dispersed in the atmosphere of civilised countries. For a thorough understanding of the kind and amount of this emission it is necessary to consider the chemical and physical characteristics of the fuel itself, its behaviour during the combustion process and the products resulting from it.

Coal is in every respect a most heterogeneous material, as is obvious from the great variety of vegetable matter which has formed the raw material, the manner of its deposition and the different biological, chemical and geophysical agencies which combined to transform this material into coal as we find it. The different kinds of coal characterised by containing four distinct rock types (vitrain, clarain, durain, fusain) in different stages of " coalification " (rank) determine the behaviour of the fuel during the combustion processes. With each of these are associated inorganic substances of characteristic composition and in characteristic proportions, together with adventitious mineral impurities derived from the strata below, above and between the coal seams.

The mechanism of combustion in a fuel bed is complicated by the fact that combination with the oxygen in the air can only take place on the

surface of a piece of coal. The rise in temperature causes layers below the surface to be subjected to thermal decomposition (carbonisation) by which combustible gas and tar are liberated. Under the aerodynamic conditions controlling the burning mechanism, some of this volatile matter escapes so rapidly from the high temperature zone that its combustion is not completed. Unless it is subjected to contact with hot surfaces such as a furnace arch, and possibly to the action of secondary air, a portion will escape in form of tar suspended in the flue gases. Some may be heated high enough to suffer secondary thermal decomposition, but only after a time lag long enough to permit its escape from the combustion zone. In this case "soot" is formed. Firing conditions permitting the escape of tar vapour or soot do not obtain in modern, well-conducted furnace operations. They are, however, the concomitant of the customary management—or lack of it—of the open fire in the domestic hearth. The tar content of deposits from the atmosphere of towns can therefore be traced back with certainty to this source and its amount forms a measure of the chimney emission from domestic fireplaces in which raw coal is burned.

The portion of the organic coal substance which is emitted from industrial furnaces or any fires operated with air and flue gas currents of high velocity, is in form of coke particles or partially burned coal particles. The former are frequently cenospheres formed by the swelling and blowing into bubbles of individual coal particles during a carbonising stage which was arrested when the empty shell was completely coked and had assumed rigidity, the hollow particle escaping from the furnace and combustion by reason of its balloon-like structure and low volume-weight. Coke cenospheres are formed in great number in pulverised fuel fired furnaces, where the sub-division of the raw coal into fine dust particles favours the occurrence of this phenomenon.

Relative to its proportion in the coal fired, the ash contributes a much greater quota of polluting matter than the combustible coal substance. The reasons for this are closely bound up with the character of the various mineral substances in the coal components and their behaviour during combustion.

The position is fairly simple in the case of burning coal in powder form. Here small coal particles, irrespective of the components they represent, are individually subjected to combustion dispersed in about 13,000 times their own volume of air, so that they are rapidly and fairly completely burned. Each particle of coal leaves its ash, again in particulate form, suspended in the flue gas. Owing to differences in their composition, these ash particles behave in different manner. Those of low fusion point are at the furnace temperature in form of liquid drops. Some of these drops, mostly in form of hollow spheres or ovoids, pass forward and retain these shapes when cooled. Many collide with each other and coalesce—as in other liquid-gas systems—or attach themselves to more refractory and still solid particles. When such aggregates become too heavy they are deposited at points determined by the velocity and the viscosity of the gases. Such sedimentation may cause the formation of masses of clinker (bird's nests). I have shown<sup>1</sup> that the size and basicity of ash particles or aggregates in a coal dust firing system diminishes from the combustion chamber towards the chimney, and that the solids emitted from the chimney may consist of highly silicious and refractory single particles.

<sup>1</sup> Lessing, *Trans. Second World Power Conference*, Berlin, 1930; *Fuel in Science and Practice*, 1930, 9, 348.

Pulverised fuel furnaces send forward about 70 per cent. of the ash in the coal fired, and dust extraction plants are therefore incorporated in most modern installations.

Coal fired in pulverised form accounts only for about 4,500,000 tons or 2.8 per cent. of this country's total consumption. The great bulk is fired in the size ranges obtained from the collieries, *i.e.*, pieces from 12 inches down to the dust particles naturally contained in coal. Some 90 per cent. of the ash remains behind, but the balance derived from coal particles detached by decrepitation or from minerals finely disseminated through the mass, is small enough in particle size to be carried by the current of combustion gases before coalescence with larger pieces can take place, and unless deposited in the flues, is emitted from the chimney.

It is worthy of note that the natural dust in coal, in which the charcoal-like fusain is concentrated, is particularly liable to be raised by the gas currents, owing to its non-caking character and consequent failure to fuse and coalesce during the carbonising stage. Much of this is therefore carried out of the fuel bed before the combustion is completed. Coal as mined contains about 4 per cent. of dust smaller than  $350\mu$ . The British consumption of 161,500,000 tons (1934) per annum included, therefore, 6,400,000 tons of this potential contribution to atmospheric pollution.

It is interesting to compare this with the total amount of solid matter found in the atmosphere, and the case of London may serve as an example. The coal consumed in Greater London in 1934 was 19,282,000 tons. Its mean dust content at 4 per cent. amounted to 771,280 tons, with an ash content of, say, 15 per cent. It may be fairly assumed that from this coal dust all its 15 per cent. ash and 7.5 per cent. of carbonaceous matter which has escaped combustion, are discharged into the atmosphere. This means a total of 173,500 tons of flue dust derived from coal dust and emitted over the 700 square miles of the London area. According to the 21st Report of the Atmospheric Pollution Committee the total deposit over these 700 square miles during the corresponding period (taking the mean of the amounts collected in all deposit gauges as representative for this area) was 184,000 tons. The portion of this total consisting of carbonaceous matter and insoluble ash plus one-half of the soluble ash (sulphates) amounts to 124,500 tons, and may be compared with the emission derived from the natural dust in coal. Whilst the pollution caused by coal dust appears to be actually greater, it must be remembered that perhaps only 15 per cent. of the solids suspended in the atmosphere settle or are washed out by rain and are caught in the gauges. Allowing for this, it appears that the natural dust in coal may be responsible for 20 per cent. of the pollution of the atmosphere with solids. As means for separating this dust are available, its elimination and utilisation under conditions permitting the collection of its ash would greatly assist in the abatement of the pollution of the atmosphere with solids.

The sulphur in coal, present partly in inorganic form in pyrites and partly in organic combination, is almost completely liberated during combustion. The greater portion escapes as  $\text{SO}_2$ , and a small portion as  $\text{SO}_3$ . I have given an estimate of the minimum annual sulphur emission over London<sup>2</sup> of 500,000 tons, expressed as sulphuric acid. Much of this remains in gas form, and a large part is retained by way of corrosion of metals, disintegration of building materials and action on textiles and

<sup>2</sup> *Nat. Smoke Abatement Soc., Proc. 7th Annual Conf., Bristol, 1935.*

other organic matter. From the point of view of disperse systems in gases, two forms must be considered; sulphuric acid nuclei present in town air, especially during fogs, and sulphate particles formed by the neutralisation of basic dust, notably lime, and oxidation during a stage of favourable  $p_H$  condition.

The presence of oxides of nitrogen ( $\text{NO}$  and  $\text{NO}_2$ ) as normal constituents of combustion gas has not received much attention in the past, but is now becoming important in connection with flue gas washing processes. Their concentration in industrial flue gases is of the order of 0.1 to 0.2 mg. per litre in terms of nitrogen, but may vary with the combustion conditions. Apart from their probable effect on the oxidation of  $\text{SO}_2$ , they are of interest in view of Coste and Wright's<sup>3</sup> work on the formation of nitrous acid nuclei.

Chlorine, which is present in many coals in amounts up to 0.5 per cent., appears in the products of combustion mainly as alkali or iron chloride, or as hydrochloric acid, and thus adds a little to the chloride content of the atmosphere derived from sea-water.

The form in which fluorine, the presence of which in some coals has been established,<sup>4</sup> is liberated on combustion is not yet known. In carbonisation it is present in the gas as hydrogen or ammonium fluoride. Though small in amount, this element will have to be regarded in future as a potential contributor to atmospheric pollution.

In the carbonising process accompanying or preceding combustion as in the domestic fire, indicated by liberation of tarry matter, ammonia is emitted which combines with  $\text{SO}_2$  or  $\text{SO}_3$  and causes the formation of water soluble nuclei. These (where dispersed in air) behave similarly to the nuclei of  $\text{NaCl}$  derived from sea-water spray.

### Dust in Mining.

Coal causes dispersion of solids in the air even before it is burned. In mining, dust is released and is carried by the currents of ventilating air and precipitated from them in the workings. The risk of its inflammation and of underground explosions caused by it is an important subject of investigation by those concerned with the safety in mines. The physical and chemical mechanism of the use of stone dust to prevent explosions requires still to be fully explained.

In the preparation of coal on the surface, the effective collection of dust from the air, notably in screening operations, is as yet an unsolved problem.

The silicious rocks associated with coal are responsible in some districts for a considerable number of cases of silicosis. The problem of the prevention of this terrible disease calls for the close study of suspension in air of particles of quartz, shale, sericite and other minerals, of sizes below  $5\mu$  formed by drilling, shot firing and other underground work. In some operations as in drilling, dispersions of the coarser dust may be avoided by suitable filters. For the fine dust raised by shot-firing, spraying with water and wetting agents is being experimented upon. Fundamental work has only recently been undertaken, and it is hoped that the results of this symposium will be of use in the practical solution of this problem.

<sup>3</sup> Coste and Wright, *Phil. Mag.*, 1935, 7, 20, 209.

<sup>4</sup> Lessing, *Nature*, 1934, 134, 699; *Fuel in Science and Practice*, 1934, 12, 347.

A better knowledge of the principles of dispersion of solids in gas will also assist on the clinical side of silicosis, for the passage of the silicious matter through the respiratory system and its retention by the lungs involve phenomena not unlike those underlying the operation of industrial filters or scrubbers.

### Methods of Cleaning Gases.

Industrial and meteorological disperse systems of solids or liquids in gases are, without exception, undesirable. The practical problems involved deal, therefore, with their breaking-up and the removal of the dispersoids from the gas phase. The methods principally employed are sedimentation in large chambers, centrifugal separation, filtration, electrical precipitation and washing with liquids in spray or film scrubbers.

Sedimentation involves the slowing down of the currents of gas carrying dust by expansion in chambers large enough in cross-section to permit the particles to settle out by gravity. Within the limits of space available in practice only the coarser particles settle effectively, although they may carry down some of the finer with which they collide in their downward path. In some cases baffles are provided to arrest particles by impact and turbulence is reduced by sub-dividing the current by means of vanes.

A common form of mechanical dust separator is the "cyclone," a cylindrical vessel into which the gas is introduced tangentially. The dust particles or droplets of liquid are thrown out by centrifugal force, arrested by friction on the wall of the cylinder and drop into the conical collecting base, whilst the gas leaves by a central tube. The efficiency for removing dust larger than  $20\mu$  may be fairly high if the apparatus is designed to keep particles once thrown to the periphery out of the turbulent zone near the vertical axis of the apparatus. Many special contrivances have been proposed to achieve this object, but the extraction of particles below  $20\mu$  requires a more intensive study of the size range and shape of each kind of dust, the temperature and viscosity of the carrying gas and a thorough exploration of the zones of streamline and turbulent flow in the vessel at varying gas velocities and pressure drops.

Filtration through fabrics or other porous layers provides a positive means of dust removal from gases. The disadvantage is the high resistance and its rise caused by the increase in the thickness of dust layers on the surface of the textile or other filter. Mechanical devices for shaking filter bags intermittently are usually employed. The permeability for fine particles varies with the original texture of the fabric, its age and condition and the thickness of the layer covering it. The need for sub-division into small units to avoid excessive resistance, makes the system very cumbersome where large volumes of gases are concerned.

In the thirty years since Sir Oliver Lodge's early experiments were applied in practice by Cottrell, electrical precipitation has been put to industrial use on an extensive scale. In broad outline the system is extremely simple. The gas to be purified is ionised by the corona discharge from negative electrodes of small radius of curvature (wires, thin rods, chains, grids); on their way to the positive, collecting electrode of large radius of curvature (tubes or plates) some of the ions attach themselves to the dispersoids, charge them and cause them to travel in the same direction. The electric current employed is of the order of 0.10 to 1.0 amps. at a pressure between 20 and 75 kv., the collecting electrode

being usually earthed. The technical development has been mainly concerned with means for producing, conducting and insulating against, the high-tension current required; with the form of the electrodes, the dimensioning of the gas passages and the design of rapping or other devices for removing dust from the positive electrode. In some cases the discharge electrode also collects some dust carried there by a minority of positively charged ions.

Much of the work done has been of an empirical kind, and was directed to the special needs of various branches of industry and the particular nature of the dusts, fogs or mists to be treated. The removal of liquids, say sulphuric acid or tar, from the collecting surfaces is easy, but dusts differ greatly in adhesiveness and conductivity and some may, by building up on the surfaces of the electrodes, affect the electrical conditions appreciably, so that non-conducting dusts may require moistening or the addition of conducting dust to the gas as well as mechanical vibration or scraping to keep the deposited layers of reasonable thickness and permeable to discharge.

The electrical precipitation industry has arrived at a stage of development where information on the properties of dispersoids, such as size, size distribution, shape, density, composition of particles, their surface properties and electrical conductivity, and the critical examination of the results will be of great assistance in its further development.

Washing of gases with water is probably the most effective method for the elimination of dispersoids in them. In gas works the scrubber packed with coke or wooden grids has served from the beginning of the industry for the extraction of ammonia and incidentally removes tar nuclei. Its modern equivalents are the rotary scrubber and towers filled with contact rings.

In air conditioning plants the control of humidity by water spraying devices is accompanied by the extraction of suspended solid particles. These plants usually incorporate eliminator baffles on which the un-vaporised excess of water in drop form is arrested.

The treatment of flue gases by wet methods has assumed considerable importance during the last few years. After the claims of the aggrieved owner of land damaged by sulphur gases from the Barton Electricity Works of the Manchester Corporation were sustained by a judgment of the House of Lords in 1929, the Electricity Commissioners insisted that at the new London power stations to be erected at Battersea and Fulham, the necessary steps should be taken to eliminate practically all the sulphur oxides from the combustion gases of their boilers before discharge to the atmosphere. The magnitude of the problem will be realised if it is considered that each of these power stations when completed and working under full load will discharge nearly 2,000,000 cubic feet of flue gases per minute, and that before washing they contain 1 grain of sulphur per cubic foot (2.3 mg. per litre) and 1.25 grains dust per cubic foot (2.8 mg. per litre).

In the preliminary work it was soon found that any method capable of extracting nearly all the sulphur will, *ipso facto*, remove the dust to at least the same degree, since dust is removed from the gas phase immediately it is wetted, whilst the absorption by water of  $\text{SO}_2$  and its oxidation to  $\text{SO}_3$  if desired, require a measurable time of contact.

The methods employed at Battersea and Fulham differ in several important respects. At Battersea<sup>5</sup> a spray system is employed common

<sup>5</sup> Hewson, Pearce, Pollitt and Rees, *Proc. Chem. Eng. Group*, 1933, 15, 67.

to all the boilers, the washing water is allowed to become acid in the first stage during which iron is added for the catalytic oxidation of  $\text{SO}_2$  to  $\text{SO}_3$ , and the effluent after neutralisation with chalk and clarification is discharged into the Thames. At Fulham an individual washer of the grid type is provided for each boiler, a lime or chalk suspension is continuously circulated in film form over the grids and only a small purge corresponding to the sulphur and dust extracted is withdrawn, clarified and returned into the cycle. The mud containing calcium sulphite, calcium sulphate and dust is discarded, but no effluent is sent into the river. In an auxiliary scrubber through which air is passed, the sulphite in the circulating liquor can be completely oxidised to sulphate, if required.

In the experimental work carried out in connection with the Fulham plant, I found that the principal difficulty did not lie in achieving the high sulphur extracting efficiency stipulated, but in preventing the incrustations of calcium sulphate deposited on the scrubbing elements. These were traced to excessive supersaturation taking place in the liquor as a result of the repeated absorption of  $\text{SO}_2$  and the oxidation of the calcium sulphite formed. Methods for de-supersaturation were evolved, which are incorporated in the Howden—L.C.I. system\* installed at Fulham and already in operation at the Tir John Power Station, Swansea.

In view of the immense fuel consumption of modern power stations, and the replacement by them of a multitude of uncontrollable point sources of pollution, the technical possibility of complete purification of their flue gas emission will prove to be an important step in the reduction of undesirable dispersoids in our atmosphere.

## GENERAL DISCUSSION.

Dr. R. Lessing, in introducing his paper, pleaded for precise definitions of the various types of dispersoids in gases. He considered that the outcome of this General Discussion would be of great value even if it only resulted in the acceptance of a reasoned nomenclature in the light of the papers submitted, quite apart from the subject-matter of the work itself.

Mr. A. G. Grant (*Darlington*) said: This paper covers a field too vast to be discussed adequately in so short a time, but our thanks are due to the author for his able review of industrial dispersions; the subject matter of the paper is, in fact, the *raison d'être* of the meetings. Apart from the more academic interest of dispersoid investigation, its main object is to evolve such an understanding of the nature and properties of suspended matter in gases as will allow of their effective avoidance or removal on the industrial scale. In few cases is it necessary artificially to produce a gaseous dispersion, whereas removal is an almost universal problem. I hope that some of us may be able to abstract and summarise the papers we have heard in the light of their industrial applications.

I would like to support Dr. Lessing in his plea for a standardised nomenclature. We have a plethora of rather vague terms—dust, mist, fog, haze, fume, and the like—and none has yet found a concise and accepted definition.

One regrets that no detailed work is reported on the formation and nature of tar fog, a dispersion of very great importance in the fuel industries,

and hopes that Dr. Lessing's reference will stimulate further basic investigation.

The occurrence of so-called gums in town's gas is an interesting case of an extreme dispersion in that the gum concentration is of the order of 10<sup>-6</sup> grammes per cubic meter.

We require much more accurate knowledge regarding the electrical precipitation process. Investigation would fall broadly into two spheres :

- (a) The " pure electric " phenomena centring round the corona discharge in various gases and with various field shapes.
- (b) The dispersoid phenomena, which can be sub-divided thus :—
  - (1) The charging of dispersoid particles and the mode of their removal from the gaseous medium.
  - (2) The phenomena and their control arising from deposition of the dispersoid on the electrodes.

These problems are fundamental to the design and understanding of electrical precipitation plant. Whilst various contributions have been made towards their elucidation, the electrical precipitation process remains as one designed and operated largely on an empirical basis. Where mathematical relations are known, these are used for comparative and co-ordinating work rather than for basic design.

**Mr. W. A. Damon** (*London*) said : I am particularly interested in that part of Lessing's paper which deals with the contamination of the atmosphere by the carbonaceous dust loosely adhering to coal. If burned in the ordinary way, much of it will certainly be emitted to atmosphere, together with the flue gas and, if as is done in some places, it is dumped on the spoil bank, it will be very likely to initiate spontaneous combustion. Many of the burning pit banks which are so prevalent in the North of England are due to the indiscriminate dumping of excessive carbonaceous matter. Therefore, I am much in sympathy with his plea for combustion under conditions which allow of the collection of the ash.

Lessing says that of the mass of solid matter suspended in the air over any area about 15 per cent. will be deposited. How did he arrive at this figure, and what happens to the remaining 85 per cent. Presumably when a South wind blows, towns to the North of London suffer more from London's pollution than from their own.

**Mr. C. H. Bosanquet** (*Billingham*) said : Dr. Pearson and myself are partly responsible for Dr. Lessing's figure of 15 per cent. for the fraction of the total emitted particles caught in deposit gauges in London. He arrived, I believe, at the figure by comparison of the deposit gauge figures with the estimated total emission, and asked our opinion on the subject.

The equations developed in our paper lead to the expectation that in fine weather only about 10-20 per cent. of the particles of diameter 20 $\mu$  will be deposited in London, and an infinitesimal fraction of particles of the order 1 $\mu$ . The remainder will drift across Europe, becoming more dilute as the cloud diffuses upwards and sideways.

The fraction 15 per cent. probably represents the fraction of the time that it is raining, when nearly all particles will be brought down near their point of origin.

**Dr. R. Lessing** (*London*), in reply, said that the figure of 15 per cent. as the proportion of the total solid matter in London air settled or washed out by rain (as determined by the deposit gauges of the Atmospheric Pollution Committee) was an estimate at which he arrived taking all known factors into account. This was confirmed by Mr. Bosanquet on a mathematical consideration of the sedimentation of particles at average wind velocities.

## TWENTY-FIVE YEARS' PROGRESS IN SMOKE ABATEMENT.

BY J. S. OWENS.

*Received 16th March, 1936.*

The selection of a title for this paper was prompted by the fact that it was in 1912 the organised investigation into the degree of atmospheric pollution by smoke commenced. The starting-point of the investigation was very definite: At a conference held at an International Smoke Abatement Exhibition in London, the following resolution was moved by the author:—

“That in the view of this Conference it is desirable that immediate steps should be taken to decide upon and secure the general adoption of a standard method for the measurement of atmospheric pollution by smoke and other products of combustion and heat, in order that the data now being collected may possess a comparative value, and that a Committee be appointed to draw up details of a standard soot and dust-measuring apparatus and methods of its use.”

The original Committee continued its work on a voluntary basis for several years. A number of Municipal Authorities had by then associated themselves with the investigation, and a grant in aid of the expenses was obtained through the D.S.I.R. The Committee then functioned as an “Advisory Committee on Atmospheric Pollution” in association with the Meteorological Office and was subsequently attached to the Air Ministry. The work continued to expand and the control of the investigation ultimately passed to the D.S.I.R., in whose hands it now is.

In attempting a review of progress made since the initiation of the investigation, certain difficulties have to be recognised. We are not in the position of having uniformly distributed observation stations over the whole country, but there is rather a tendency to concentrate stations in the more highly polluted neighbourhoods. This is a perfectly natural result since such places are likely to be more concerned with the condition of their atmosphere than would be, for example, a sea-side resort far removed from any manufacturing area. However, one effect of this is that when attempting to estimate the condition of the air of this country as affected by smoke pollution, allowance has to be made for this concentration. One way of examining the changes which have occurred would be to take each station individually and compare the result obtained year by year, and this in some respects is the most satisfactory. In the case of large cities where a number of stations have been established, the average of the stations may be taken and, provided they retain the same position, may be compared with a view to finding what improvement, if any, has resulted.

In this paper the details of the methods adopted for measurement will not be dealt with, but rather the general results obtained. It may, however, be stated briefly that the measurement upon which most reliance is based is an estimation of the weight of matter deposited from

the air upon a measured area at or near ground level. A standard deposit gauge has been evolved for this purpose and is in use at about 100 different stations throughout the country.

In addition to the measurement of deposit, the suspended matter is also examined by a different method, *i.e.* by filtration through white paper leaving a stain which, in smoke-polluted cities, can be made to give a measure of the degree of pollution of the air by sooty matter.

The desirability of reviewing the progress made to date will be evident since it will be seen from what follows that the rate of improvement of the air of our cities is by no means as great as it should be, and the author hopes that the condition set forth in this paper will make it evident that greater efforts must be made in the direction of smoke abatement if we are to obtain any marked and continued improvement.

Since this investigation started there have been in operation 158 stations making official reports. These, however, have not all been in operation at the same time, nor have they all continued from the beginning until now. Hence it becomes necessary to make some selection of stations in examining the variation of the deposit. This has been done by excluding from the comparison any station with less than eight consecutive years' observations, except in one or two exceptional instances.

The reports made of deposited impurity show this analysed into soluble and insoluble matter, and experience has shown that the amount of rainfall in any year has a marked effect upon the amount of soluble matter deposited, but little effect upon the insoluble. Hence we must not compare individual years but rather find some method which will show the trend over a longer period of years. Again the insoluble matter deposited has been divided into tar, carbonaceous matter and ash, and the soluble into loss on ignition and ash, while the soluble matter has also had the amount of sulphates, chlorine and ammonia estimated.

In such an examination as this and in order not to burden the paper with too many figures it is advisable to select a few of the more important elements of the deposit for consideration. It has, therefore, been decided to compare upon the basis of total solids deposited from the atmosphere in any year, the deposit of sulphates found in the soluble matter and the amount of tar deposited. Before dealing with the individual stations, it might be well to give the reasons for this selection :—

The total solids deposited gives a gross measure of the pollution reaching the ground from the air, although it is not all derived from the smoke or grit from chimneys, it may at least be regarded as atmospheric pollution. Some of the deposited matter is undoubtedly derived from wind-blown dust, and hence it is found that the insoluble part of the deposit tends to be higher in summer than in winter, whereas the soluble part tends to be higher in winter than in summer.

The selection of sulphates deposited is based upon the fact that the main source of pollution of the atmosphere by sulphur is from the combustion of fuel containing sulphur. In addition, it is one of the most dangerous products and is injurious to health and vegetation as well as to building material; while, being derived from the combustion of fuel, it is some measure of the pollution from this source. Unfortunately the sulphate emitted from a chimney is in an invisible form and is, therefore, not eliminated by eliminating visible smoke. It follows also that efforts to attack visible smoke do not necessarily reduce the amount of sulphur pollution in the air, and it has to be dealt with independently by some of the methods recently adopted successfully in our large power stations.

Tar is pre-eminently a product of bituminous coal burnt in domestic

fires. Hence it is included as some measure of the degree of pollution by domestic smoke. It is well known that the soot from domestic smoke contains a high percentage of tar, often up to 30 per cent., whereas that from boiler furnaces or other well designed furnaces contains little or no tar.

The above reasons will explain why these three elements of pollution have been selected to give a reasonable measure of the progress made in the prevention of pollution of the air.

The stations examined are shown in the tables below for the years available and a brief summary of the position may now be given referring to the attached tables :—

In dealing with the progress of events, it will be best to take individual cities because the conditions in different cities vary very much, and it will be observed from the tables that, whereas in some cases there has been improvement, in others this is not the case.

**London.**—In this case the figures shown are an average for eight stations, and, as in all other tables, they represent the deposit from the air estimated in English tons per square mile. We have here a consecutive series of twenty years with no break, and these should give a very fair picture of the course of events. Starting at 1915/16 we find the deposit of total solid matter was 415 tons per square mile, 72 tons of sulphates and 4 tons of tar. Following this there was a fairly steady improvement until 1921/22, that is for seven years, and this improvement shows up as a reduction in total deposit and in deposit of sulphates. In this year 1921/22 the total deposit had fallen to 284 tons per square mile and the sulphates to 25 tons. In the following years between 1921 and 1935, the total deposit has altered very little, there have been some ups and downs, but it would not be very wrong to say that the conditions have remained practically unaltered. It is not quite so satisfactory when we look at the sulphates deposited, as here we find actually an increase, although not very great. So that while in 1921/22 there was a deposit of 25 tons, in 1934/35 this had increased to 49 tons per square mile, while tar remained unchanged. Here then we find a state of affairs which is not very easy to explain, but at any rate it can be said that there is no great ground for optimism as regards the condition of the air of London during the last fourteen or fifteen years.

**Glasgow.**—Here also we have an unbroken series of twenty years' observations, and the figures are an average of nine stations. In some respects it follows curiously the behaviour of London. In 1915/16 the total deposit was 422 tons per square mile, 92 tons of sulphates and 4 tons of tar. This diminished regularly until 1921/22 when we find a total deposit of 255 tons, and 34 tons of sulphates per square mile. Since then for the next fourteen years there have been some ups and downs but no general improvement can be observed. In 1934/35 the total deposit was 268 tons per square mile including 37 tons of sulphates, while tar remained unchanged.

The cause of this curious behaviour in the two cities is not by any means obvious, and may be a suitable subject for speculation and discussion at a meeting such as this.

**Wakefield, W.R. Rivers Board.**—This gauge is in the centre of the city in a manufacturing and residential area. There is a period of eleven years with one or two breaks which do not affect the sequence very much, and, so far as total deposit from the air and the deposit of sulphates are concerned, Wakefield shows a continuous improvement. The deposit in 1924/25, the first year available, amounted to 613 tons per square mile, while sulphates amounted to 136 tons and tar 8 tons. In 1934/35 this was reduced to 225 tons per square mile total deposit, 24 tons sulphates and 6 tons tar, a very creditable state of affairs.

**Bournville Works.**—This gauge is 4 miles S.W. by S. of Birmingham. There are ten years' consecutive records and a fairly constant history of

improvement, but not anything very spectacular. Starting in 1924/25 with 192 tons per square mile of total deposit, 17 tons of sulphates and 2 tons of tar, we finish in 1934/35 with 173 tons of total deposit, 18 tons of sulphates and 1 ton of tar.

**Bournville Village.**—This gauge is  $4\frac{1}{2}$  miles S.W. of Birmingham in a residential area. Here we have nine years' records, and a slight improvement is also indicated. In 1925/26 the total deposit amounted to 157 tons per square mile, the sulphates to 18 tons and the tar to 1 ton, while in 1933/34 the figures had fallen to 93 tons per square mile of total deposit, 11 tons of sulphates and 1 ton of tar. This behaviour is somewhat similar to that of Bournville Works, it shows an improvement but not a very great one.

**Birmingham Central.**—There are ten years' records and again a history of improvement, but not very great. Starting in 1922/23 with a total deposit of 419 tons per square mile, sulphates 50 tons and tar 4 tons, we finish in 1931/32 with 340 tons per square mile of total deposit, 27 tons of sulphates and 4 tons of tar. This is a somewhat similar history to the Bournville records: This is for the centre of the city.

**Cardiff.**—This gauge is also in the centre of the city. We have nine years available at Cardiff, commencing at 1926/27 with a total deposit of 368 tons per square mile, sulphates 21 tons and tar 9 tons. This improved until 1930/31 when there was 133 tons total deposit, 22 tons of sulphates and 2 tons of tar. After that the improvement was not maintained, but with some ups and downs we arrive at 140 tons per square mile total deposit, 17 tons of sulphates and 1 ton of tar in 1934/35.

**Gloucester.**—This shows a fairly constant improvement for the nine years of which we possess records. It commences in 1926/27 with 343 tons per square mile total deposit and finishes in 1934/35 with 117 tons per square mile. In this case we have no record of sulphates or tar.

**Leicester, Town Hall.**—This gauge is less than  $\frac{1}{2}$  mile S.S.E. of the centre of the city. There are only eight years' records here, commencing in 1927/28 with 370 tons per square mile total deposit, 42 tons sulphates and 3 tons tar. There was very little improvement noticeable until 1933/34 when there was a definite drop in the deposit, and in 1934/35 the total deposit amounted to 259 tons per square mile, sulphates 24 tons and tar 4 tons. We may rank this city as having improved at any rate during the last couple of years.

**Newcastle, Westgate.**—The gauge is approximately  $\frac{1}{2}$  mile west of the centre of the city. We have ten years' observations commencing 1925/26, and a fairly constant history of improvement up to 1934/35. The total deposit amounted to 443 tons per square mile, the sulphates 69 tons and the tar 13 tons in 1925/26; these figures had fallen to 292 tons total deposit, 35 tons sulphates and 8 tons tar in 1934/35.

**Newcastle, Town Moor.**—This gauge is  $1\frac{1}{2}$  miles north of the centre of the city in fairly open country. It has the same series of years and shows a somewhat similar history to that at Westgate, but not such a marked improvement. The total deposit in 1925/26 was 268 tons per square mile, the sulphates 45 tons and the tar 4 tons, while in 1934/35 these figures had dropped to 236 tons per square mile total deposit, 42 tons sulphates and 6 tons tar.

**Rothamsted.**—This gauge is 1 mile S.W. of Harpenden Town in open country in a residential district. Rothamsted is a country station which gets most of its pollution by drift from London or other cities. There are sixteen years' observations, and a definite improvement during this period although not a very constant one. In fact most of the improvement occurred in the first four years when the deposit fell from 245 tons in 1919/20 to 86 tons per square mile in 1922/23. There were ups and downs after this until 1934/35 when the total deposit was 83 tons per square mile. We may, therefore, say that the last twelve years show practically no improvement.

**Rochdale, Technical School.**—Here we have twelve records covering the years 1916/17 to 1927/28, and there is, on the whole, an evidence of reduction of deposit based upon the total solids. Starting in 1916/17 with 731 tons per square mile, we finish in 1927/28 with 584 tons.

To continue with the story of Rochdale, as the Technical School gauge did not continue beyond 1927/28, we have to use the records from another gauge, i.e. at the Town Hall, and while these figures must not be taken as representing the same conditions as held at the Technical School, they may be compared amongst themselves for improvement or otherwise. In the Technical School gauge the observations of sulphates and tar were not carried out, but these were estimated in the Town Hall gauge.

**Rochdale, Town Hall.**—This gauge is in the centre of a manufacturing city. We have a period of eight consecutive years' observations here, and if we base our conclusions on total solids the deposit drops from 350 tons per square mile in 1927/28 to 236 tons in 1934/35. The sulphates and tar, however, do not tell quite the same story, and as these are specifically combustion products, they are perhaps more reliable. Thus in 1927/28 there was a deposit of 38 tons of sulphates per square mile, and 4 tons of tar, while in 1934/35 the respective figures were 40 and 4, showing no improvement.

**Burnley, Town Hall.**—There are nine years' observations available here, and the station is very remarkable in the sense that a sudden improvement occurred after three years, and the low level was maintained subsequently. In 1925/26 the total deposit amounted to 860 tons per square mile, 117 tons of sulphates and 25 tons of tar. In 1927/28 the figures were respectively 856, 137 and 11. There was a sudden drop next year to a total deposit of 464 tons per square mile, sulphates 31 tons and tar 10 tons, and the condition remained more or less the same as regards total solids and sulphates until 1933/34, the final figures being total solids 427 tons per square mile and sulphates 31 tons. There was, however, a definite increase in the quantity of tar deposited, which, increased steadily up to 30 tons per square mile in 1933/34, an excessively heavy deposit. There is no obvious explanation of the sudden reduction in the amount of deposit, but the fact that it occurred simultaneously in the total solids and in the sulphates suggests that there was a definite reduction in the amount of smoke. This gauge is in the centre of the city in a manufacturing district.

The cities which show at least some improvement in the amount of deposit from the air have been dealt with first, and we will now examine those which show no improvement or a falling back.

**Leeds, Headingley.**—The gauge is in a residential area 3 miles from the centre of the city. We have twelve years of observations, and the history is not one of continuous improvement, but rather the reverse. Commencing in 1923/24 with 12 tons total deposit, 13 tons sulphates and 1 ton per square mile of tar, we finish in 1934/35 with 122 tons per square mile total deposit, 14 tons sulphates and 1 ton tar.

**Leeds, Hunslet.**—This gauge is in an industrial area  $1\frac{1}{2}$  miles from the centre of the city. Here again we have thirteen years' records and somewhat the same story. There is practically no difference between the condition now and twelve or thirteen years ago. In 1922/23 the total deposit amounted to 305 tons per square mile, the sulphates to 25 tons and the tar to 5 tons. In 1934/35 the figures were 301 tons of total deposit, 23 tons of sulphates and 3 tons of tar per square mile.

**Leeds, Park Square.**—The gauge is  $\frac{1}{2}$  mile from the centre of the city in a densely populated area. There are thirteen years' observations available, commencing 1922/23 when the total deposit was 305 tons per square mile, sulphates 29 tons and tar 5 tons. These figures have altered very little until 1934/35 when the total deposit amounted to 338 tons per square mile, the sulphates to 23 tons and the tar to 3 tons. Thus in the total impurities deposited in the air we find no improvement, but there is a slight improvement in the sulphates and tar.

**Leeds, York Road.**—This gauge is 1 mile from the centre of the city in a densely populated working-class district. Here we have twelve years' observations and the figures tell the same story as at Park Square. Commencing 1923/24 with a total deposit of 247 tons per square mile, 25 tons of sulphates and 3 tons of tar, we finish in 1934/35 with 292 tons of total deposit, 24 tons of sulphates and 4 tons of tar. Thus these stations in Leeds indicate no improvement in the condition of the atmosphere.

**Liverpool, Netherfield Road.**—The gauge is  $1\frac{1}{2}$  miles N.N.E. of the Town Hall in a manufacturing and very thickly populated area. There are fourteen years' observations, starting in 1921/22 when the total deposit was 548 tons per square mile, sulphates 52 tons and tar 4 tons. Conditions have not improved since then, in fact there is evidently more pollution in the atmosphere, since the total deposit in 1934/35 was 590 tons per square mile, sulphates 66 tons and tar 5 tons.

**Marple.**—This gauge is in open country tending to become suburbanised. We have eleven years' observations at Marple commencing in 1924/25 with a total deposit of 102 tons per square mile, 38 tons of sulphates and 2 tons of tar. The total deposit shows no improvement during the following ten years, but sulphates and tar do show a reduction. The figures for 1934/35 were 105 tons per square mile of total deposit, 21 tons of sulphates and 1 ton of tar.

**St. Helens.**—The gauge is in the centre of the city. We have eighteen years' consecutive observations here commencing 1917/18 with 612 tons per square mile total deposit, 99 tons of sulphates and 13 tons of tar. These figures fell rapidly during the subsequent three years, and in 1920/21 the total deposit was 371 tons per square mile, the sulphates 59 tons and the tar 4 tons. After that the improvement was not maintained, but in some years, the conditions went back and in 1934/35 the total deposit amounted to 431 tons per square mile, sulphates 30 tons and tar 9 tons. Looking at the column of sulphates deposited here there is a period from 1927/28 to 1934/35 when there was a continuous reduction in the sulphates, this was not, however, reflected in the tar or total deposit.

**Stoke-on-Trent, Leek Road.**—This gauge is in the centre of the city in a manufacturing area. We have available eleven years' observations commencing 1924/25 and the position disclosed is not very satisfactory. In 1924/25 the deposit of total solids was 192 tons per square mile with 21 tons sulphates, while in 1934/35 this had risen to 232 tons of total deposit and 29 tons of sulphates. As will be seen there has been a gradual deterioration, not entirely continuous.

At Castleford, Garston and Edinburgh, where there are not a great number of years for comparison, the indications are of a fairly steady condition of impurity. There are slight variations from year to year, but hardly anything which can be regarded as evidence of improvement or deterioration.

We could thus divide the stations referred to in this paper into three groups, the first in which a definite improvement has been indicated in the degree of pollution of the air. This group includes London, Glasgow, Wakefield (W.R. Rivers Board), Bournville Works and Village, Birmingham Central, Cardiff, Gloucester, Leicester Town Hall, Newcastle (Westgate and Town Moor), Rothamsted, Rochdale (Technical School and Town Hall), and Burnley. In the second group there has been an equally definite deterioration. This group includes, Leeds (Headingley, Hunslet, Park Square and York Road), Liverpool (Netherfield Road), Marple, St. Helens, and Stoke-on-Trent (Leek Road), while the third group shows little or no change in the condition of the air and includes Castleford, Garston and Edinburgh.

It is necessary to remember that a certain selection has had to be made of the available stations for reference in this paper. It is hardly possible to give a definite answer to the general question "Is the

TABLES SHOWING THE AMOUNT OF IMPURITY DEPOSITED IN TONS PER SQUARE MILE (ANNUAL TOTAL).

1934/35	268	37	3					1934/35	298	49	5
1934/36	239	28	3					1935/36	284	43	4

condition as to smoke pollution improving in this country or otherwise." It will be seen from what has already been said that improvement may be going on in one place and deterioration in another, and it would not be fair, for example, to take two such places and by averaging them conclude that the general condition was unaltered. It is true that the smoke emitted in any city is not confined to its own boundaries, but spreads over the whole country, and in this sense there is a general pollution of the air which might be estimated as distinct from the local pollution produced in a specific neighbourhood. Possibly the condition of Garston might be taken as representing this general rather than local pollution, since the station is situated well out in the country and produces little smoke pollution in its own neighbourhood.

The lesson to be learnt from the foregoing is fairly obvious: The fact that certain cities have reduced the pollution of their air very much is proof that it can be done with care and attention, and might be given as an answer to any doubts raised by other cities as to their ability to reduce smoke. The condition in this country at present is by no means satisfactory, and it is obvious that we should put a great deal more energy and effort into smoke prevention than we are doing. This might be taken as the lesson to be learnt from the cities of groups two and three. It is, however, not the cities only which suffer from the smoke pollution: it is astonishing the degree of pollution of the air in the open country to leeward of a great city such as London. The track of the smoke cloud extends for many miles down wind and the concentration of smoke is so great even in the open country under such conditions that far more attention should be given to it by Public Health Authorities. The

author has often experienced a dense smoke haze, easily visible in a room, at a distance of 12 miles S.W. of London. Given suitable conditions which impede the dispersion of the smoke cloud from the city, that is, a low wind velocity and an inversion of the vertical temperature gradient overhead, then the smoke drifts along with little reduction in its concentration. The author has seen on the coast of Devonshire a thick smoke haze through which the sun had a deep orange colour, and he has traced this haze to the manufacturing districts in the Midlands. This paper is, however, intended to be rather a review of progress since the beginning of the investigation than a pointing out of lessons, and indeed they are sufficiently obvious to need little indication.

### GENERAL DISCUSSION.

Mr. C. F. Goodeve (*London*) said: In welcoming us to Leeds the Vice-Chancellor of this University expressed a hope that we would close our discussion in a happier frame of mind than we had commenced it and that, before many years, we would do something to relieve the irritations of housewives, etc. From the title of this paper one receives a certain amount of encouragement, but it is misleading. This adequate summary given by Dr. Owens shows conclusively that, except for a few cities during the five-year period from 1915, no reduction in any of the impurities deposited from the air has been found and, in a good many cases, there is a serious increase.

An important question for the consideration of this meeting is "What is being done, or what is proposed to be done, with regard to the situation?" We have an active society which carries on extensive propaganda work. We can only hope that it will receive increased support and that its efforts may produce some improvement.

There is also "The Atmospheric Pollution Research Committee." Their very interesting annual reports contain, amongst other things, the results of an enormous number of determinations of the deposits from the air in different cities in this country. The available statistics now cover millions of observations. Some years ago, I attempted to make a statistical analysis of these figures. Beyond showing what Dr. Owens has discussed in this paper, the results of this analysis were disappointing. Mr. Wilsdon, however, has persevered further and obtained a number of curves which are given in the last Report. In this connection, I should like to quote from his paper the following sentence (p. 51):—

"Whatever may be the true interpretation of the early data, it does not seem possible to advance much further by examination of existing records."

It would appear that Mr. Wilsdon agrees with me that the large amount of work involved in obtaining these statistics is not leading to any definite conclusions. These figures cover a period of twenty-one years. I would ask the members of this committee, most of whom are present, seriously to consider whether it is possible to direct some of the enormous amount of labour involved in obtaining these statistics along more useful lines.

I am not familiar with the terms of reference under which this committee is appointed, but I would venture to suggest that they might find practical means to help the situation by, for example, advising local authorities or even investigating for them the causes of atmospheric pollution. One finds in the reports for a number of years that unusually high deposits were found in the neighbourhood of Ravenscourt Park, London. I would like to ask the committee whether the cause of this high deposit was ever found and if so, were any steps taken to remove it.

The most encouraging aspect of the whole question comes from the amount of independent work which is being done by private companies for the improvement of atmospheric pollution. The London Power Company are among the pioneers in this work. When one considers the large amount of private consumption of coal which will be replaced by electricity produced from a practically pollution-free power station, one can appreciate that the Battersea Power Station will produce no small improvement in the conditions obtaining in London. In this connection, I would like to quote from Dr. Coste's paper to this discussion :

"Dust from leaves in Battersea Park, near the Power Station, was mostly domestic and horticultural in origin, very few spheres being found, showing the efficiency of the gas-washing plant."

In addition to the work of the London Power Company, there are also the highly successful experiments of Imperial Chemical Industries carried out at Billingham and described in Nonhebel's paper to this discussion. As a result of their work it is now possible to instal an efficient plant for the smallest of industrial chimneys. There remains no excuse for the pollution of the atmosphere by the small factory.

We all look forward to the opening of the Fulham Power Station in London and feel confident that it will be as successful as the others. There are also a considerable number of gas washing plants for power stations in various parts of the country, but the small factory is very slow in responding.

Aside from this independent work, we have little to satisfy our minds as to the future. Chemistry and engineering have solved most of the practical problems involved and the matter is now largely a political one. It is to be hoped that the civic authorities in this city will take a leading part and, before long, Leeds will lose its title of "The City of Perpetual Mourning."

**Professor F. G. Donnan** (*London*) said he thought that Mr. Goodeve's criticisms were unjustified. The Atmospheric Pollution Committee had done an immense amount of excellent work in devising methods of measurement and obtaining quantitative data. They could not be blamed for any failure on the part of Municipal and Government Authorities to take action.

**Dr R. Lessing** (*London*) pleaded for a survey of the sources of atmospheric pollution as distinct from the observation of the incidence and effects. For this purpose, a limited number of types of coal-consuming plants and appliances should be investigated. Whilst the total emission may not have been reduced in amount in the 20 years during which observations have been made, the character had changed, mainly in the direction of a diminishing soot and tar content and an increasing proportion of ash dust and coke particles.

**Dr. G. M. B. Dobson** (*Oxford*) said : As I have some responsibility for the work of the Atmospheric Pollution Research Committee, I should like to make some explanations in view of Mr. Goodeve's friendly criticisms of this work.

Firstly, it is entirely outside the scope of this Committee to initiate work on methods of reduction of smoke from either domestic or factory chimneys, or to test existing methods. Their work is to devise methods for the accurate measurement of the pollution existing in the air, and to advise local authorities of the best methods they should use in measuring the pollution in their towns. It is not even the duty of the Committee to make the routine observations of pollution all over the Kingdom, this being the duty of Local Authorities. In certain special cases the Committee do make observations, but their small income would have to be multiplied many times if they were to be responsible for all the observations now being made by the local authorities.

The Committee are responsible for advising what type of pollution should be measured, and it is entirely due to them that the method of measuring gaseous  $\text{SO}_2$  was worked out by the Government chemist at

their special request, and at the expense of their funds. In this connection I would also mention that the question of the possible presence of droplets of  $H_2SO_4$  has been much discussed by them, and the work which Mr. Coste (a member of the Research Committee) reported to this Conference, is a direct result of this. So far as I know, this is the first time an accurate measurement of the amount of  $H_2SO_4$  in city air has been made, and the suggestion that a method had been worked out by the Government chemist several years ago but not used by the Committee is not correct.

**Mr. G. Nonhebel** (*Billingham*) said: The higher deposits of sulphates in Central London may well be due to the increasing use of coke for central heating in the office districts. Coke contains more sulphur in relation to its calorific value than coal, and the coal used for coking has usually in any case a higher sulphur content than best quality domestic coal.

With the growth of large centrally situated power stations there is now a strong case for the use of low pressure pass-out steam for heating in densely populated areas (particularly in towns like Leeds, where the domestic smoke from closely packed houses, often back to back, is so serious in the valleys) and close to one of the power stations. By this means a large proportion of the latent heat of the steam which is now lost in the condenser water would be saved.

For such a scheme to be tried, it would really be necessary to have a State-aided large-scale experiment, and to forbid the use of open fires in the district under investigation.

In New York City one of the central heating stations has a boiler output of 500 tons/hour. The visibility in this city is generally far better than that in London, owing to the absence of open domestic fires. The main problems there are, however, the elimination of grit and  $SO_2$  from the chimneys of the large power stations, particularly in the Tudor City district where many of the buildings tower above the chimneys of two large power stations.

**Dr. J. S. Owens** (*London*), in reply (*communicated*): In reply to Mr. Goodeve's remarks, I would first refer to his last paragraph, in which he says that "chemistry and engineering have solved most of the practical problems involved and the matter is now largely a political one." This is really the heart of the whole question. If I might paraphrase Mr. Goodeve's statement, I would put it in this form: "So far as the prevention of smoke pollution from industrial processes is concerned, we are in a position to prevent this if we want to, and the continued existence of a polluted atmosphere from this cause is evidence of the lack of a sufficiently strong public desire to prevent it." This brings me to the suggestions as to the work of research on atmospheric pollution. I do not agree with Mr. Goodeve that the statistics obtained are not leading to any definite conclusion. The work done has shown clearly the degree of pollution of the air and the improvement which can, and has been affected in certain places. It will, I think, be generally accepted that if a problem like this is to be tackled, the first essential is some means of measuring, both to enable us to realise the extent of the evil and to indicate the degree of success attending efforts made to reduce it. The title usually applied to the work, that is "The Investigation of Atmospheric Pollution," is perhaps a little vague as to the specific nature of the investigation intended. The object in view was strictly one of measurement. Of course, this does not invalidate any criticism such as that another object should have been included, or might still be included, but the particular problem attacked was quite sufficient in view of the funds available.

In reply to the query as to the heavy deposits in Ravenscourt Park, London, the exact source of these deposits has not been found, nor have the Committee initiated any steps to remove it. This is a case, where such action would be outside the terms of reference of the Committee.

# THE INFLAMMATION OF DUST CLOUDS.

BY R. V. WHEELER.

*Received 2nd March, 1936.*

A cloud of fine dust in air behaves in many respects similarly to a gas or vapour. If the dust is inflammable, its similarity to a gas in behaviour extends to its ability to propagate flame if it is present in sufficient concentration in the air.

Dusts vary in their degree of "inflammability" (*i.e.* in their ability to propagate flame when they form clouds in air) with their chemical composition and their fineness. It is not so easy to obtain a direct measure of the inflammability of a dust as it is of a gas or vapour. It is not easy, for example, to determine accurately the dilution limits (lower and upper) such as are usually sufficient to define the inflammability of a gas or vapour.

An indirect measure of the inflammability of a dust can be obtained by making use of the fact that the admixture with it of a sufficient quantity of an incombustible dust (stone dust) can render it incapable of propagating flame. Such a measure has been used more particularly for assessing the relative inflammability of coal dusts, mainly because a practical method of rendering harmless the dust produced during coal-mining is to treat it with stone dust. Two examples of the problems studied regarding the inflammability of coal dusts will be considered: (1) The effect of the concentration of the dust (of constant composition and fineness); and (2) the effect of the fineness of the dust (of constant composition and concentration).

## The Effect of the Concentration of the Dust on its Inflammability.

The method of experiment used was, briefly, to determine the amounts of a chosen stone dust, intimately mixed with the coal dust and of the same degree of fineness, required just to prevent the continued propagation of flame when the mixtures were strewn along an explosion gallery and ignited by a standard source of ignition.

The explosion gallery was constructed of steel tubing 4 ft. in diameter, and was 325 ft. long. It was closed at one end. A known quantity of an intimate mixture of coal dust and stone dust (Fuller's Earth), prepared by hand from materials pulverised so that between 80 and 85 per cent. could pass through a 200-mesh (I.M.M. standard) sieve,\* was spread evenly on the floor of the gallery. The means of ignition was a blown-out shot of 20 oz. of gunpowder, tightly stemmed with 8 in. (1. lb.) of coal dust. The shot was fired from a small cannon with a 2-in. bore placed on the floor of the gallery at a distance of 15 ft. from the closed end, with its muzzle pointing towards the open end. An open-ended steel tube, 1 ft. in diameter and 6 ft. long, was arranged immediately in front of, and in line with, the cannon. A quantity of the dust mixture to be tested, such that there were 1½ lb. of coal dust (irrespective of the proportions of coal dust and stone dust in the mixture), was strewn evenly within this tube.

\* Throughout this paper, the meshes of sieves referred to are I.M.M. standard.

A series of tests with a number of loadings of a chosen coal dust was made, different proportions of stone dust being used at each loading until two mixtures were found of which one propagated flame throughout the gallery and the other, containing  $2\frac{1}{2}$  per cent. more stone dust, merely extended the flame of the cannon-shot by 75 to 175 ft.

The results of crucial experiments with a coal dust of average inflammability are recorded in Table I.

TABLE I.—THE EFFECT OF THE CONCENTRATION OF COAL DUST ON ITS INFLAMMABILITY.

Expt. No.	Composition of Mixture per Cent.		Concentration in Gallery (oz. per cu. ft. of gas).		Result Length of Flame.

For the concentrations of dust recorded in this table in ounces per cubic foot capacity of the gallery, the assumption is made that all the dust strewn on the floor of the gallery was raised in suspension in the air either by the concussion produced by the cannon-shot or during the subsequent propagation of flame. The results are shown graphically in Fig. 1. The "upper limit" of concentration for this coal dust was not obtained. No experiments were made with concentrations of coal dust higher than 1.425 oz. per cubic foot of air. This concentration, for a mixture containing 52.5 per cent. of stone dust, amounts to about  $2\frac{1}{2}$  lb. of mixture per linear foot of the gallery and such quantities as would be required to reach the upper limit, judging by the slope of the curve in Fig. 1, would have presented considerable obstruction in the gallery.

During an experiment in which the loading of dust along the gallery was initially heavy, the concentration of dust in the air was probably neither initially uniform nor continuously maintained as the flame travelled but was affected by the degree of turbulence created ahead of the flame. The initial inflammation might raise the whole of the dust as a dust cloud and the flame, after travelling a short distance, might begin to slacken speed by reason of the cooling action of the large excess of dust. The checking of the flame in this manner would reduce the amount of turbulence ahead of it and much of the dust would fall out of suspension in the air, leaving a concentration more favourable to the propagation of

flame. It was noted that the progress of flame along the gallery when it had been heavily loaded with dust was slow and spasmodic.

The "lower limit" of concentration of this coal dust (under the conditions of test) was about 0.07 oz. per cubic foot of air, and the optimum concentration, which was sharply defined, was 0.23 oz.

FIG. 1.—The effect on its inflammability of the concentration of coal dust in air.

With a coal dust of low inflammability by reason of its chemical composition, the amount of stone dust required to suppress inflammation, even at the optimum concentration, is small. Such a coal dust was therefore used in a series of experiments designed to test the possibility of determining an upper limit of concentration. The results are recorded in Fig. 2.

FIG. 2.—The effect on its inflammability of the concentration of coal dust in air.

An analogy can be drawn between these experiments and gaseous inflammations. Thus, Coward and Hartwell<sup>1</sup> have determined the limit of inflammability of firedamp in atmospheres containing carbon dioxide. Their results are shown graphically in Fig. 3, where the concentration of methane in the air is plotted against the concentration of carbon dioxide required to suppress inflammation. The concentrations of the gases are expressed as percentages by volume.

<sup>1</sup> *Safety in Mines Research Board Paper, No. 19.*

### The Effect of the Fineness of the Dust on its Inflammability.

The physical quantity that measures the fineness of a particle of coal dust most significantly with respect to its reactivity, and thus with respect to its inflammability, is its specific surface, *i.e.* the ratio of its surface to its mass. Sufficiently accurate (relative) values for the specific surface of coal dust samples can be decided from their sieving analyses, whereby the proportions of particles of different sizes are measured.

FIG. 3.—The effect on its inflammability of the concentration of methane in air.

Tests of the effect of the fineness of a coal dust on its inflammability were made in a similar manner to those on the effect of its concentration, using a coal which was as inflammable (by reason of its chemical composition) as that used for the experiments recorded in Table I. The stone dust used was, as before, Fuller's Earth, 85 per cent. of which would pass through a 200-mesh sieve, and all the tests were made with the optimum concentration of coal dust.

TABLE II.—THE EFFECT OF THE FINENESS OF COAL DUST ON ITS INFLAMMABILITY.

Preparation.	Sieving Analysis, per Cent.							Index of Inflammability.	
	3-5.	5-8.	8-20.	20-50.	50-100.	100-200.	Through 200.	Stone Dust, S, per Cent.	Ratio 100/(100-S).

J.	12	29	23	16	6	6	8	5	1.05

Nine preparations of the coal were made, to provide dusts of different degrees of fineness, by the use of coarse and fine grinding in different mills and by blending the products. Table II. records sieving analyses of these preparations, together with their "inflammabilities" expressed (a) as percentages of stone dust, S, in the mixtures through which (at optimum concentration) flame just failed to propagate when tested in the explosion

TABLE III.—FINENESS FACTORS FOR SIEVED FRACTIONS OF COAL DUST.

Mesh of Sieve.	Width of Mesh. Inch.	Mean Diameter of Particle (D). Inch.	Fineness Factor, $\left(\frac{0.00375}{D}\right)$ .
3	0.1667	0.1333	0.028
5	0.1000	0.0813	0.046
8	0.0625	0.0438	0.086
20	0.0250	0.0175	0.214
50	0.0100	0.0075	0.500
100	0.0050	0.00375	1.000
200	0.0025		

gallery, and (b) as the ratios  $100/(100 - S)$ , which show the amounts of mixed coal dust and stone dust which unit quantity of coal dust just failed to render inflammable. The use of the latter index greatly simplifies discussion of the relationship between fineness and inflammability.

From general inspection of Table II. it is evident that the inflammability of a coal dust is affected in a marked degree by the proportion of through

FIG. 4.—Relationship between fineness and inflammability.

200-mesh dust that it contains. The results of the tests with Preparations G, D and E, which contained nearly the same proportion through 200-mesh, show also that as the total amount of through 50-mesh dust is decreased the inflammability decreases.

**Assessing the Fineness of the Dust Preparation.**—It can be assumed that the speci-

fic surface of a dust particle is inversely proportional to its mean diameter, and that the average mean diameter of the particles in a sieved fraction is the mean of the widths of the two meshes between which the fraction lies. A proportional factor can then be assigned to each sieved fraction of a dust preparation, except that which passes through the finest sieve. To that fraction an arbitrary factor must be assigned. This method has been used to assess the relative fineness of the preparations used for the tests of

inflammability. The factors used for each sieved fraction are recorded in Table III.

With these factors for each sieved fraction, together with an arbitrary value 2.000 for the fraction passing through a 200-mesh, the composite fineness factor,  $F_o$ , for each of the dust preparations has been calculated from its sieving analysis, as shown in Table IV.

TABLE IV.—THE FINENESS FACTORS ( $F_o$ ) OF THE COAL DUST PREPARATIONS.

Preparation.	3-5 (0.0028).	5-8 (0.046).	8-20 (0.086).	20-50 (0.214).	50-100 (0.500).	100-200 (1.000).	Through 200 (2000).	Fineness Factor $F_o$ .
A.	—	—	—	—	0.005	0.14	1.70	1.85
B.	0.001	0.003	0.005	0.009	0.010	0.13	1.30	1.46
C.	—	—	0.003	0.034	0.115	0.22	0.72	1.09
D.	—	—	0.003	0.071	0.065	0.14	0.72	1.00
E.	0.002	0.008	0.011	0.021	0.020	0.10	0.76	0.92
F.	—	—	0.025	0.045	0.035	0.11	0.64	0.86
G.	—	—	0.034	0.062	0.055	0.09	0.22	0.46
H.	0.002	0.010	0.021	0.041	0.040	0.07	0.24	0.42
J.	0.003	0.013	0.020	0.034	0.030	0.06	0.16	0.32

In Fig. 4 the factors  $F_o$  for the preparations are plotted against their inflammability indices,  $100/(100 - S)$ . The graph shows a linear relationship which can be expressed by the formula:  $100/(100 - S) = 1.1 F_o + 0.7$ , whence  $S = 100 - 100/(1.1 F_o + 0.7)$ .

Any deviation from the relationship expressed by this formula is within the limits of experimental error of 2.5 per cent. stone dust for the determination of inflammability.

## THE SPREAD OF SMOKE AND GASES FROM CHIMNEYS.

By C. H. BOSANQUET, M.A., AND J. L. PEARSON, B.A., PH.D.

*Received 11th March, 1936.*

### I. Introduction.

The authors have dealt elsewhere<sup>1</sup> with the following theoretical and practical aspects of the spread of chimney emissions:—

- a physico mathematical analysis of the phenomena involved in eddy diffusion;
- space-concentration distribution and mass-over-area distribution of emission from point and from line sources;
- the effects of chimney height on space-concentration and mass-over-area distributions.

Mass-over-area distribution of atmospheric pollution from chimney emissions is of practical importance, since it determines:—

- in rainy weather, the amount of acid and dust brought down by the rain,
- in fine weather, the extent of the curtailment of sunshine and ultra-violet rays.

<sup>1</sup> *J. Inst. Elec. Eng.*, July, 1935, and *J. Inst. Fuel*, April, 1935.

Space-concentration distribution governs the general environment of pollution, to which buildings and people are subjected when it is not raining, the effects from acids being dependent on and those from dust being largely independent of humidity. In a sense, ground level concentrations should not be of great practical importance, since, in any civilised community, they are presumably already maintained below the extent to which they become actively inimical to health or injurious to vegetation.

In this paper the mathematical analysis of the phenomena involved in eddy diffusion is carried further, with results that indicate that :—

- (a) any reasonable theoretical treatment of the subject-matter, utilising any reasonable assumptions, leads to closely identical conclusions carrying similar practical implications ;
- (b) the earlier and more general treatment of the subject, as mentioned above, presents a fairly correct picture of the mechanism and effects of eddy diffusion, and is reasonably consistent with ascertained facts and experimental data.

This paper, however, presents a more acceptable theory concerning vertical diffusion.

It should be noted that, in practice, no theoretical assumptions at all have to be made in order to determine :—

- (a) the mass-over-area distributions from continuous emission by point or line sources, as averaged over long intervals of time, say a year ;
- (b) similar distributions over short intervals of time when the wind is swinging, to and fro, through an angle of the same order as that of the cone of discharge.

With regard to distant ground concentrations arising from sources of continuous emission and as averaged either over long periods of time or over shorter periods with average wind swing, the only assumption is that concerning the effects of vertical diffusion. Up to distances of, say, fifteen chimney heights from the source, there can be little doubt about the ground concentrations, owing to the emission taking a form which is so often visible.

The authors wish to call attention, in particular, to the widespread misconceptions that have existed in the past concerning :—

- i. chimney height : It can now be clearly shown that any increase above a reasonable height has no practical effect.<sup>1</sup>
- ii. concentration at moment of emission : This is really of very little importance indeed in practice, the most important factor in the problem of atmospheric pollution being the mass rate of emission of the objectionable constituents for any and every particular case.

## II. The General Case of Eddy Diffusion (i.e. for a single Dispersing Cloud).

In a wind gases and dust will be dispersed more rapidly than in still air, since eddy diffusion arising from the effects of turbulence in the dispersing medium will be superimposed on the effects of kinetic diffusion and Brownian motion. Eddy diffusion coefficients found in practice vary considerably, but, in all cases, they are very large compared to the ordinary coefficients of the kinetic theory. The effects of these latter can be neglected in comparison.

In eddy diffusion the variations of velocity from place to place correspond to velocities of agitation, and the average distance an

<sup>1</sup> For a suggested criterion of reasonable height see *J. Inst. Elec. Eng.*, July, 1935.

individual portion of gas moves before losing its sense of direction corresponds to the free path.

G. I. Taylor<sup>3</sup> has shown that there is no need to postulate anything definite about the type of motion of individual portions of gas in order to investigate the spreading of such properties as composition and momentum. All that is necessary is to assume that the correlations at different times between the vector velocities and the properties of the portion of the gas are functions of the time difference, the correlation decreasing from unity to zero with increasing time difference. The following analysis differs considerably from his, but is based on the same fundamental ideas.

Consider a gas in which a property  $C$  varies along the  $x$  axis. Let the root-mean-square velocity fluctuations of individual portions of gas be  $u$ . Let  $v$  be the velocity component along the  $x$  axis, and let  $F(t)$  be the correlation between the values of  $v$  of the same portion of gas at times differing by  $t$ . Also, if the value of  $C$  varies from one portion of gas to another, let the correlation between the deviations of  $C$  from the mean of the surroundings at times separated by  $t$  be  $f(t)$ . If  $f(t)$  is independent of the deviation from the mean, then the probable deviation will decrease by equal percentages in equal time, so that

$$f(t) = e^{-Kt}.$$

Consider the case of a portion of gas whose velocity component along the  $x$  axis at the zero of time is  $v$ . At time  $-t$  let it be in a region where the mean value of  $C$  is  $C_0$ , then when  $t = 0$  the probable value of  $C$  of the portion considered is given by:—

$$\int_0^\infty K C_t e^{-Kt} dt \quad . \quad . \quad . \quad . \quad (1)$$

At time  $-t$  the probable value of  $dx/dt$  is equal to  $vF(t)$ , so that the probable value of  $x$  is:—

$$x_0 - v \int_0^t F(t) dt,$$

and the probable value of  $C_t$  is therefore:—

$$C_0 - v \frac{dC}{dx} \int_0^t F(t) dt \quad . \quad . \quad . \quad . \quad (2)$$

Combining equations 1 and 2, the probable value of  $C$  can be found as a function of  $v$ . If for instance,  $F(t) = e^{-Lt}$  then the probable value of  $C$  will be:—

$$C_0 - \frac{v}{K+L} \cdot \frac{dC}{dx} \quad . \quad . \quad . \quad . \quad (3)$$

This leads to a diffusion coefficient

$$D = \frac{u^2}{3(K+L)} \quad . \quad . \quad . \quad . \quad (4)$$

Any assumptions as to the form of  $f(t)$  and  $F(t)$  will yield an expression of this type.  $D$  is proportional to  $u^2$  divided by the sum of two terms,  $K$  a rate of mixing term, and  $L$  a rate of loss of momentum term.  $K$  is obviously proportional to  $D$  and  $L$  is proportional to the effective kinematic viscosity of the gas. Now the kinematic viscosity is the diffusion

<sup>3</sup> *Proc. Lond. Math. Soc.*, 1922, 20, 196.]

tend to increase as  $u$  increases. Hence, both  $u$  and  $\int_0^\infty \phi(r) dr$  increase with the size of the cloud.

The problem can also be dealt with by dimensional analysis. The diffusion coefficient can be assumed to depend only on :—

the wind velocity . . . . .	$v$
the kinematic viscosity . . . . .	$\nu$
some undefined length . . . . .	$l$

The kinematic viscosity here is the ordinary kinematic viscosity, not the kinematic eddy viscosity.  $l$  may be the height above ground, the mean radius of the cloud, the distance the cloud has drifted from its source, or some kind of weighted mean of all three. In any case, the relation must hold that

$$D = \nu l f\left(\frac{\nu l}{\nu}\right) \quad (6)$$

If  $D \propto \nu$ , as suggested above, then  $f\left(\frac{\nu l}{\nu}\right)$  must be a constant, it is also a matter of common experience in hydraulics and aero-dynamics that large scale phenomena are uninfluenced by viscosity, leading to the same conclusion.

It can therefore be assumed that  $D$  is very nearly proportional to  $\nu l$  for phenomena on a meteorological scale.

If the standard deviation  $\sigma$  be defined as the root-mean-square of the displacements of the constituents of a cloud from a plane passing through the centre of gravity and normal to the direction in which diffusion is being considered, then by the ordinary laws of diffusion

$$\frac{d\sigma}{dt} = \frac{D}{\sigma}.$$

If a cloud has its origin at ground level, and cross-sections of the cloud after drifting different distances downwind are similar then  $\bar{z}$ , the mean height above ground, is proportional to  $\sigma$ . If, therefore,  $l$  can be identified with  $\sigma$  or  $\bar{z}$ , and if  $D \propto \nu$ , it can be seen that  $d\sigma/dx$  is constant where  $x$  is the distance the cloud has drifted from the source. Thus  $x$ ,  $\bar{z}$  and  $\sigma$  are all proportional to each other, and it makes no difference except to the numerical constant which of them is identified with  $l$ .

This analysis leads to the conclusion that  $\sigma \propto x$ . Now, the cross-section of a cloud from a continuous point source such as a chimney is proportional to  $\sigma^2$ , so that the mean density in such a cloud varies as the inverse square of the distance from the source. It is shown by Sutton<sup>4</sup> that an inverse square law of decrease of density is a limiting case corresponding to perfect correlation between the motions of a portion of air at all times. He gives evidence, however, to show that the law is very closely approached in practice, so that variations of the turbulence of the air with weather conditions and with the nature of the ground will probably cause far greater errors in calculated values of the mean cross-section of a cloud at various distances than will a small deviation of  $\pi$  from unity in the formula  $D \propto \sigma^2$ .

### III. Diffusion of a Gas Constituent from a Continuous Line Source.

A. In deriving a formula for the concentration of flue gas in the atmosphere at different points downwind from a chimney, it is convenient to treat the horizontal and vertical diffusions separately. The two diffusions will follow rather different laws owing to the effect of the ground, so that vertical diffusion takes place in a semi-infinite space instead of an infinite space.

Consider first a continuous line source of atmospheric pollution such as a row of chimneys, which is long compared to  $\sigma$ .

It can be seen by watching a persistent smoke cloud coming from a chimney that, at points a few chimney heights away downwind, the cloud sometimes appears to be in contact with, and sometimes rises clear of the ground. It is necessary, therefore, to consider either the maximum instantaneous pollution density at a point or else the average over a time long compared with the time of passage of an eddy. This long time average will be considered here.

In this case it is necessary to take account of vertical movements of the centre of gravity of the cloud as well as of the spreading of the cloud, since the average concentration at any point is equal to the product of the average concentration when the cloud overlaps the point and the fraction of the total time during which overlap occurs. For a cloud whose sinuosities are large compared to its diameter, the average concentration inside the cloud varies inversely as the square of the diameter and the time varies almost directly as the square of the diameter, so that the time average depends almost entirely on the amplitude of the sinuosities, and is nearly independent of the actual diameter of the cloud. The diffusion coefficient in the vertical direction then depends only on the root-mean-square of the vertical component of the wind velocity and on  $\phi(r)$ . These are both independent of the presence or absence of the cloud, so that  $D$  must be independent of both  $x$  and  $\sigma$ , and  $l$  must therefore be identified with  $z$ , the height of the point above ground.

The diffusion equation can therefore be written

$$D = p\sigma v \quad . \quad . \quad . \quad . \quad . \quad . \quad (7)$$

where  $p$  is a numerical constant.

If diffusion can be neglected in the horizontal plane, *i.e.* if the source is a line source giving no cross wind variation of  $C$ , and if the concentration gradient in the direction of the wind is small compared to the vertical concentration gradient, then :—

$$\frac{dC}{dt} = p\sigma \frac{d}{dz} \left( z \frac{dC}{dz} \right),$$

$$\text{or} \quad \frac{dC}{dx} = p \frac{d}{dz} \left( z \frac{dC}{dz} \right) \quad . \quad . \quad . \quad . \quad . \quad . \quad (8)$$

It appears an extraordinary conclusion at first sight that the diffusion coefficient should be least near the ground where the turbulence is expected to be greatest; however, the effect of the ground is to reduce the correlation between values of velocities at neighbouring points, *i.e.*

to reduce  $\int_0^\infty \phi(r) dr$ . Further, components of velocity normal to a surface must vanish at that surface.

## B. Derivation of a Formula for Concentration at Ground Level due to a Line Source at Finite Height.

If a line source situated at a height  $h$  above ground emits a mass  $M$  of some constituent per unit length in unit time, then if the wind velocity is  $v$  at all points

$$\int_0^\infty C dz = \frac{M}{v} \quad . \quad . \quad . \quad . \quad . \quad (9)$$

Combining equations 8 and 9, a complete solution can be obtained for the special case  $h = 0$  in this case ;

$$C = \frac{M}{pvx} e^{-\frac{z}{px}} \quad . \quad . \quad . \quad . \quad . \quad (10)$$

In the general case, it is possible to analyse the distribution in the plane  $x = 0$  into a series of exponentials similar to a Fourier series, so that the combined effect of a number of positive and negative line sources at ground level, at points upwind of the actual source, will combine to produce a line source of strength  $M$  at height  $h$  in the plane  $x = 0$ .

If the virtual sources are of strengths  $A, B, C$ , etc., situated at  $x = -d, x = -d/2, x = -d/3$ , etc., then the conditions to be satisfied are :—

$$A + B + C + \dots = M$$

$$C = \frac{1}{pvd} \left( Ae^{-\frac{z}{pd}} + 2Be^{-\frac{2z}{pd}} + 3Ce^{-\frac{3z}{pd}} + \dots \right) \rightarrow 0,$$

when  $z$  is unequal to  $h$ .

These conditions are satisfied if  $\frac{pd}{h}$  is vanishingly small and

$$A = Me^{\frac{h}{pd}}$$

$$B = -\frac{M}{2!} e^{\frac{2h}{pd}}$$

$$C = \frac{M}{3!} e^{\frac{3h}{pd}}$$

$$\text{If } \frac{h-z}{pd} = \psi.$$

Then

$$C = \frac{M}{pvd} e^{\psi - e^\psi}.$$

This expression is obviously vanishingly small for moderately large positive or negative values of  $\psi$ , and as  $d$  is decreased indefinitely, the distribution approaches more and more closely to a line source at height  $h$ .

For positive values of  $x$  :—

$$C = \frac{M}{pvx} \left\{ \frac{e^{\frac{1}{p} \left( \frac{h}{d} - \frac{z}{x+d} \right)}}{1 + \frac{d}{x}} - \frac{e^{\frac{2}{p} \left( \frac{h}{d} - \frac{z}{2x+d} \right)}}{2! \left( 1 + \frac{d}{2x} \right)} + \frac{e^{\frac{3}{p} \left( \frac{h}{d} - \frac{z}{3x+d} \right)}}{3! \left( 1 + \frac{d}{3x} \right)} - \dots \right\} \quad (11)$$

The only place where the value of  $C$  is important is ground level, so that the special case of  $z = 0$  will be considered.

Let 
$$u = e^{\frac{h}{pd}}.$$

Then 
$$d = \frac{h}{p \log u}.$$

Substituting this value in equation 11, and expanding the series in powers of  $u$  and  $\frac{d}{x}$  gives:—

$$C = \frac{M}{pux} \left\{ \left( u - \frac{u^2}{2!} + \frac{u^3}{3!} - \dots \right) - \frac{h}{px \log u} \left( u - \frac{u^2}{2 \cdot 2!} + \frac{u^3}{3 \cdot 3!} - \dots \right) + \frac{h^2}{p^2 x^2 \log^2 u} \left( u - \frac{u^2}{2^2 \cdot 2!} + \frac{u^3}{3^2 \cdot 3!} - \dots \right) - \dots \right\}.$$

$C$  is given by the limit of the sums of these series when  $u$  tends to infinity.

The sum of the first series is obviously  $1 - e^{-u}$ , and if each series be divided by  $u$  and then integrated with respect to  $u$  the result is the succeeding series.

The sums of the series for large values of  $u$  are therefore equal to:—

$$1, \log u + K, \frac{\log^2 u}{2!} + K \log u + L, \text{ etc.}$$

Where  $K, L$ , etc., are numerical constants.

$$\begin{aligned} \therefore C_0 &= \frac{M}{pux} e^{-\frac{h}{px}} \left( 1 - \frac{Kd}{x} + \dots \right) \\ &= \frac{M}{pux} e^{-\frac{h}{px}} \quad \dots \quad \dots \quad \dots \quad \dots \quad (12) \end{aligned}$$

since  $d$  is vanishingly small.

$C_0$  is a maximum when  $x = \frac{h}{p}$ , and when  $x$  is large compared to  $\frac{h}{p}$ , the exponential term becomes unity, and  $C$  falls off inversely as the distance.

### C. The General Case where $D = pux^n$ .

Comparison of equations 10 and 12 shows that the value of  $C$  at ground level due to a source at height  $h$  is the same as the value at height  $h$  due to a source at ground level. This is also obviously true for a diffusion coefficient independent of height, and may be assumed to be generally true for any law of diffusion.

The general equation:—

$$\frac{dC}{dx} = p \frac{d}{dz} \left( z^n \frac{dC}{dz} \right)$$

can be solved for a source at ground level, so that if the above theorem be used

$$C_0 = \frac{2-n}{\Gamma\left(\frac{1}{2-n}\right)} \cdot \frac{M}{v(px)^{\frac{1}{2-n}}} e^{-\frac{h^{2-n}}{px}} \quad \dots \quad (13)$$

The maximum value of  $C$  occurs when  $px = (2-n)h^{2-n}$ , and the maximum concentration varies between  $0.48 \frac{M}{vh}$  for  $n=0$  and  $0.37 \frac{M}{vh}$  for  $n=1$ .

The value of the concentration at the maximum is thus seen to be almost independent of the law of variation of diffusion with height and quite independent of the value of the turbulence constant  $p$ .

#### IV. Diffusion of Dust from a Continuous Line Source.

Equation 12 is derived on the assumption that no matter is lost from the cloud, and that gravity is without effect. In the case of dust particles, a steady fall must be superimposed on the dispersion, and all particles which strike the ground will be assumed to be retained. The result of this will be that the total mass of the cloud will decrease with distance.

Again, consider the case of an infinite line source of strength  $M$ , and let the free falling speed of the particles be equal to  $f$ .

The diffusion equation now becomes :—

$$\frac{dC}{dx} = p \frac{d}{dz} \left( z \frac{dC}{dx} \right) + \frac{f}{v} \cdot \frac{dC}{dz} \quad . \quad . \quad . \quad (14)$$

and

$$\frac{d}{dx} \int_0^\infty C dz = - C_0 \frac{f}{v} \quad . \quad . \quad . \quad (15)$$

Equation 14 is equation 8 with a term added to allow for the fall of the particles, and equation 15 gives the rate of loss of mass from the cloud due to the settling out of the particles.

If the source is so distant that the effect of height of emission is negligible, the solution of these equations is :—

$$C = \frac{A}{x^{1+\frac{f}{pv}}} e^{-\frac{z}{pz}} \quad . \quad . \quad . \quad (16)$$

In the case of a gas  $f = 0$ , and for a very distant source  $C$  and  $C_0$  are expressed by equations 10 and 12 respectively for a source at height  $h$  at any distance. The formula for the case of dust must be of the same type as that for a diffusing gas, since the latter is a limiting case of the former. At small distances from the source, the falling of the dust will tend to increase the ground concentration, and at great distances the reduction of total mass of the cloud will cause it to fall below that given by the gas formula.

If the ground concentration is independent of  $f$  at a distance  $X$ , then a possible form of the formula is

$$C_0 = \frac{MX^{\frac{f}{pv}}}{pvx^{1+\frac{f}{pv}}} e^{-\frac{h}{pz}} \quad . \quad . \quad . \quad (17)$$

Since all the dust will eventually settle, and the amount settling on unit area in unit time is equal to  $C_0 f$ , we have the relation

$$\int_0^\infty C_0 f dx = M.$$

If  $f/pv$  is small, this condition is satisfied by equation 17 if  $X = 1.78 \frac{h}{p}$ . then

$$C_0 = \frac{M \left( 1.78 \frac{h}{p} \right)^{\frac{f}{pv}}}{pvx^{1+\frac{f}{pv}}} e^{-\frac{h}{pz}} \quad . \quad . \quad . \quad (18)$$

No formal proof of this formula has been obtained, but it is of the right form and gives the correct values for large values of  $x$ , and small values of  $f/pv$ . An additional check can be obtained by evaluating

$$\int_0^{\infty} C_0 dh = M/v.$$

This gives the value of  $C_0$  due to an infinite vertical plane source emitting a mass  $M$  per unit area per unit time. At all points downwind of such a source, the value of  $C$  must be  $M/v$ , since no concentration gradients are present, and consequently there is no diffusion. This gives additional confirmation to equation 18. At great distances, then, the ground level concentration of dust from an infinite line source at any height above ground will fall off rather more rapidly than the inverse first power of the distance, the falling off being more rapid the larger the particles.

### V. Diffusion from a Continuous Point Source.

If the source is concentrated at a point such as the top of a chimney, instead of being spread over an infinite line across wind, the lateral spreading must also be taken into account.

Here the duration of the sample time is of even more importance than in the case of vertical diffusion from a line source. If a really long sampling period be required, *e.g.* if it is desired to estimate the average atmospheric pollution during the whole year, then the governing factor will be the distribution of direction of the wind. The instantaneous width of the smoke cloud will be without effect in this case, since increase of width will decrease the average concentration in the cloud and increase the frequency with which the cloud overlaps any given point, the two effects exactly cancelling each other.

If the fraction of the year during which the wind direction falls within an arc  $\theta$  be  $a\theta$ , and the mean wind velocity be  $v$ , then the average value of  $C$  for the whole year due to a chimney emitting a mass  $M$  of gas per unit time will be

$$\frac{Ma}{pvx^2} e^{-\frac{a}{v^2 x^2}} \quad . \quad . \quad . \quad . \quad . \quad (19)$$

The mean value of  $a$  will obviously be  $\frac{1}{2\pi}$ , and the variation of  $a$  with direction can be obtained from meteorological records, and is independent of any diffusion theory.

Equation 19 gives the value of  $C$  which is effective in all cumulative processes, such as the blackening of the neighbourhood by soot, and to a great extent the attack of structures by acid constituents of flue gas such as oxides of sulphur and nitrogen and HCl.

At points not far distant from a chimney, effects due to the maximum concentration over short periods may become of importance, *e.g.* the gases may be smelt, and in this case the effective sampling period can be taken as of the order of a few minutes to an hour, *i.e.* a period during which the mean wind direction is not likely to change appreciably.

In this case, at points which are situated at a distance from the chimney smaller than the velocity of the wind multiplied by the mean duration of the minor transitory changes of direction, the lateral spreading of the mean cloud will be governed by the swing of the wind and equation 19 will hold with a suitable value of  $a$ .

If  $\sigma$  be the standard deviation referred to a vertical plane through the mean axis of the cloud, then

$$\sigma \propto x.$$

Now

$$\frac{d\sigma}{dt} = \frac{D}{\sigma}.$$

$$\therefore \frac{d\sigma}{dx} = \frac{D}{v\sigma}.$$

If, therefore,  $\sigma \propto x$ , then  $D \propto \sigma v \propto vx$ . At distances such that  $\sigma$  is great compared to  $h$ ,  $\bar{z} \propto x$  and, as pointed out above, in these circumstances in the formula  $D \propto vl$ , it makes no difference whether  $l$  be identified with  $\sigma$  or  $\bar{z}$ . Again, therefore, at great distances  $D \propto \sigma v$ , so that  $\sigma/x$  is constant.

In the case of gas emission, the total mass of unit length of the cloud will be everywhere equal to  $M/v$ . The mass  $m$  over unit area of the earth's surface at a distance  $x$  downwind, and  $y$  to one side of the mean path of the cloud, must be a maximum when  $y = 0$ , and fall off to zero at values of  $y$  large compared to  $\sigma$ . If the diffusion coefficient be assumed to be a function of  $x$  or  $\sigma$  only, and independent of  $y$ , and if concentration gradients along the cloud be assumed small compared to those at right angles to its mean direction of motion, then

$$\frac{\partial m}{\partial x} = \frac{D}{v} \cdot \frac{\partial^2 m}{\partial y^2}.$$

These conditions are satisfied by the equation

$$m = \frac{M}{\sqrt{2\pi\sigma v}} e^{-\frac{y^2}{2\sigma^2}}. \quad (20)$$

If  $D = qv\sigma$  then  $\sigma = qx$ .

$$\therefore m = \frac{M}{\sqrt{2\pi qvx}} e^{-\frac{y^2}{2q^2x^2}}. \quad (21)$$

Substituting this value of  $m$  for  $M$  in equation 12 gives for the ground level concentration due to a continuous point source,

$$C_0 = \frac{M}{\sqrt{2\pi p q v x^2}} e^{-\frac{h^2}{p^2 x^2} - \frac{y^2}{2q^2 x^2}}. \quad (22)$$

Similarly, for the case of dust with a free falling speed of  $f$ ,

$$C_0 = \frac{M \left( 1.78 \frac{h}{p} \right)^{\frac{f}{p^2}}}{\sqrt{2\pi p q x}^{\frac{2}{p^2}} e^{-\frac{h^2}{p^2 x^2} - \frac{y^2}{2q^2 x^2}}}. \quad (23)$$

## VI. Comparison with Experiment and Numerical Values of $p$ and $q$ .

The value of  $p$  can be estimated in various ways. Hellmann,<sup>5</sup> from experiments over an open field at heights of from 2 to 32 metres, found that the wind velocity varied approximately as  $s^{1/5}$ . This is in general agreement with the observation that the velocity of a gas flowing in a

<sup>5</sup> *Met. Z.*, 1915.

pipe varies in the region of the pipe wall proportionally to the  $1/7$  power of the distance from the wall. A later formula of Hellmann gives

$$v = a \log(z + b) - c,$$

where  $a$ ,  $b$  and  $c$  are constants.

The mean of Hellmann's first formula and the pipe results gives  $\frac{dv}{dz} \propto z^{-5/6}$ , and Hellmann's second formula gives  $\frac{dv}{dz} = \frac{a}{z+b}$ . Now the product of the velocity gradient and the effective eddy viscosity must be constant and equal to the tangential force per unit area on the ground. Since the diffusion coefficient can be identified with the kinematic eddy viscosity, these two formulæ indicate that  $D \propto z^{5/6}$  and  $D \propto z + b$  respectively, agreeing reasonably well with the assumption made in this paper that  $D \propto z$ . An approximate estimate of  $p$  can be made from the first formula. It is known that above about 500 metres the wind velocity agrees well with the value calculated from the horizontal barometric pressure gradient. Also the tangential force per unit area on a plane for large scale phenomena tends to the limiting value of about  $0.002 \rho V^2$ , where  $V$  is the velocity at points remote from the plane. If then the velocity be assumed to vary as  $z^{1/6}$  up to 500 metres, after which it becomes constant, then

$$\frac{dv}{dz} = \frac{V}{6(5 \times 10^4)^{1/6}} z^{-5/6},$$

$$\text{and} \quad 0.002 \rho V^2 = \rho D \frac{dv}{dz},$$

$$\therefore D = 0.073 V Z^{5/6}.$$

If  $v$  be the velocity of the wind at 100 metres, then the value of  $D$  at 100 metres is  $0.02 v z$ . This gives  $p = 0.02$ , a value which is probably too low, since the tangential force of  $0.002 \rho V^2$  was obtained by experiments with smooth pipes and the tangential force on the earth's surface may well be considerably greater. If a cloud from a chimney be viewed from the side, then the opacity is probably a function of the total amount of matter in the line of sight. The apparent density will be equivalent to that from a line source, since lateral spreading is without effect on the opacity. The apparent greatest density at ground level then will occur when  $px = h$ , or at a distance  $1/p$  chimney heights from the source.

Dobson,<sup>6</sup> in a memorandum on atmospheric turbulence, gives a composite of eight successive photographs of a smoke cloud from a chimney. The maximum density at ground level is apparently about seven chimney heights from the source, giving  $p = 0.14$ . He states that on another day the apparent turbulence was 0.4 times as great, giving  $p = 0.06$ . In this case, there were a number of buildings immediately to leeward of the chimney, so that more turbulence would be expected than in Hellmann's case.

Experiments by Richardson<sup>7</sup> on smoke clouds from small sources near the ground give a mean standard deviation in the vertical direction of 0.45 m. at a distance of 5 m. from a source 2 m. above ground. This leads to a value of  $p$  of 0.01, but these experiments again were carried out over a smooth field where the turbulence would be expected to be low.

<sup>6</sup> Advisory Committee for Aeronautics, Reports and Memoranda No. 671, 1919.

<sup>7</sup> *Phil. Trans.*, 1920, 221A, 1.

An average value of  $p$  is probably about 0.05, with possible variations by a factor of at least 3 in either direction. This value would make the apparent greatest density at ground level of the smoke cloud from a chimney occur at a distance of twenty chimney heights, whilst the actual maximum density, allowing for lateral diffusion, would occur at half this distance.

### B. The Value of $q$ .

Experiments by Richardson and Porter<sup>8</sup> on the horizontal scatter of small balloons released nearly simultaneously and drifting distances of between 30 and 600 km. give a mean value of  $\sigma$  in the horizontal direction of 16 km. at a distance of 200 km. the best fit to their points being obtained if  $\sigma \propto x^{0.9}$ . This gives a mean value of  $q$  of 0.08 over this range of distances.

Now, the value of  $\sigma$  for horizontal diffusion is  $qx$ ; but for vertical diffusion from a source at ground level if  $D = pv$ , then  $\sigma = \sqrt{2} px$ . If, therefore,  $\sigma$  is the same in the horizontal and vertical directions, and the cross-section of a smoke cloud is roughly circular or semi-circular, according to whether it is formed at a great height or near the ground, then  $q = \sqrt{2}p$ . This indicates a value of  $p$  of 0.057 from the balloon results, in agreement with the mean value at short distances.

### C. Sootfall in and near Towns.

It has been deduced above that the rate of deposition of dust at a distance  $x$  from a line source of intensity  $M$  is equal to

$$\frac{Mf}{pv} \cdot \frac{\left(1.78 \frac{h}{p}\right)^{\frac{1}{pv}}}{x^{1 + \frac{1}{pv}}} e^{-\frac{h}{px}},$$

where  $h$  is the height of the source above ground.

The D.S.I.R. Report on Atmospheric Pollution for 1931 gives an account of experiments which were carried out in the neighbourhood of Norwich. Norwich can be considered in this case as a line source of smoke about 2 miles in length. At distances between 2 and 10 miles from the centre of the city the rate of dust deposition at points immediately downwind varied as  $A + B/x$ ,  $A$  being the rate of deposition of non-city dust. This agrees with the formula above if  $f/pv$  and  $h/px$  are both small. The value of  $f$  for a 20 micron diameter coal particle in air is 1.5 cm./sec., the mean value of  $v$  is about 500 cm./sec., and  $p$  can be taken as 0.05.

For particles of this size,  $f/pv = 0.06$ . The mean height of the chimneys of Norwich is probably about 15 metres, so that at a distance of 2 miles from the centre of the city,  $e^{-h/px}$  will vary between 0.83 and 0.94. This difference from unity is partially compensated by the effect of the finite depth of the city, the mean value of  $1/x$  being  $\frac{1}{2} \log_e 3 = 0.55$ , instead of 0.50 at a distance of 2 miles from the centre of the city. It would be expected, therefore, that the inverse first power law would hold with reasonable accuracy, as was found in practice.

It will be noticed that although there is a considerable range of values of  $p$  deducible from different sets of experiments, yet there is no apparent tendency for  $p$  to decrease as the scale of the experiments is

<sup>8</sup> *Mem. Roy. Met. Soc.*, 1925, 1.

increased; in fact, the smallest values are deduced from the smallest scale experiments (Richardson). If  $n$  is appreciably less than unity in the expression  $D = pvs^n$ , then the value of  $p$  deduced on the assumption that  $n = 1$  should fall off with distance from the source according to the law  $px^{\frac{1-n}{2-n}} = \text{const.}$

This confirms the statement made above that effects due to the deviation of  $n$  from unity are unimportant compared to the variations of  $p$  with conditions of weather and surface.

## VII. General Conclusions and Applications.

A theory has been developed by dimensional analysis for calculating the spreading of a smoke cloud from a chimney, and the results have been

FIG. 1.

shown to agree reasonably well with experiment. At points close to the chimney the concentration at ground level is small, since but little smoke has diffused down to the ground. At a distance of the order of ten times the height of the chimney the smoke concentration at ground level reaches a maximum. The concentration at that maximum varies inversely as the square of the chimney height, and its actual value is almost independent of assumptions as to the variation of diffusion coefficient with height. At greater distances the concentration at ground level falls off again until after about fifty chimney heights the concentration varies as the inverse square of the distance and is independent of chimney height.

A formula is given for the concentration at all distances from the chimney foot.

Assuming that  $p = 0.05$  and  $q = 0.08$

$$C_g = \frac{100 M}{11x^2} e^{-\frac{204}{x}} - \frac{78q^2}{x^2}.$$

The figure gives values of  $\frac{C_0}{M}$  for various values of  $x$  for a chimney one hundred metres high, with a wind velocity of 5 m./sec.  $C_0$  is in milligrammes per cubic metre,  $M$  is in metric tonnes per day, and the values are those for  $y = 0$ , i.e. at points on the ground directly under the axis of the cloud. The upper curve gives values of  $C_0$  if  $h = 0$ , i.e. the difference between the two shows the effect of chimney height in reducing the atmospheric pollution at ground level. With a chimney 100 metres high the concentration is halved at 2.9 km., and at greater distances the effect of chimney height becomes progressively smaller. Over the range of distances covered by the curve the variation of dust concentration with distance is indistinguishable from that for gases, since the curves intersect at 3.56 km, and the slopes are very nearly the same for particles of the order of 20 microns diameter. This is not surprising, since in the absence of diffusion, coal particles 20 microns in diameter would not reach ground until they had drifted 33 km.

It may be pointed out that the general form of the curves is independent of any theory as to the variation of diffusion with height. In particular, the ratio of the yearly average contaminations produced by different types of source such as a power station and a town, at distances great compared to the chimney heights are independent of all theory. This point is stressed because this investigation was originally begun in order to find whether the superposition of the products of combustion of a power station in a town on those of domestic fires would cause an appreciable increase and in order to estimate the improvement attainable by using tall chimneys.

It is seen that although the improvement is great in the immediate locality, yet a mile or two away the effect of chimney height disappears completely.

### GENERAL DISCUSSION.

**Mr. F. I. G. Rawlins** (*London*) said: It would be of great use to those who have to consider the influence of fogs and dust upon buildings and their contents if they could be provided with a three-dimensional scheme showing, not only the amount of material deposited at ground level at given distances from a chimney, but also the vertical distribution. Clearly, local conditions would influence the relationships enormously, but any method of obtaining a rough idea of the amount of deposit to be expected on the roof of a building of given height at a given distance from a chimney would be of considerable practical value. One imagines that fog and dust "shadows" are presumably cast by large obstacles, and this could be allowed for if some indication of vertical distribution could be obtained as a function of the other two variables.

**Mr. G. Nonhebel** (*Billingham*) said: It has been shown from the principles of eddy diffusion that the maximum ground concentration occurs at a distance of the order of ten chimney heights from the base of the chimney. A curve for one particular set of circumstances is given by Pearson and Bosanquet in Section VII. of their paper. For other circumstances, the maximum ground concentration  $C_0$  in mgs./M<sup>2</sup> at the centre of the line of discharge will be roughly

$$C_0 = \frac{1.55 \times 10^3 M}{v h^2},$$

where  $M$  = mass rate of emission in tons/day,  $v$  = wind velocity in m./sec.  $h$  = chimney height in m. From this it may be deduced that when the wind-velocity is relatively low at 2 m./sec. and the emission is 60 tons SO<sub>2</sub>/day, the maximum ground concentration with a chimney height of 330 ft. (100 m.) is 5 mgs. SO<sub>2</sub>/M<sup>2</sup>. (A diagram showing the progressive

increase in chimney height required to keep the ground concentration below 5 mgs./M<sup>3</sup> has been recently published.)<sup>1</sup> This is not an unreasonable factor of safety, and yet few of the larger power stations fulfil this condition.

It is evident that further experimental observations are urgently required on diffusion of smoke from chimneys, and biological experiments on the toxic effects of SO<sub>2</sub> and SO<sub>3</sub> are similarly required. It would be of interest, also, to know how much of the SO<sub>2</sub> in an atmosphere is oxidised to SO<sub>3</sub> when it is dissolved in the moisture in the lungs.

Mr. C. H. Bosanquet (*Billingham*) said in reply: Measurements of numbers and size distributions of particles in the air at different distances from the source would be of great use in testing the theory. The size distribution should only vary very slowly with distance for particles less than 20 $\mu$  in diameter.

In reply to Rawlins: Small particles in the air will diffuse as a gas so that no true shadows can be produced by buildings. If a building is close enough to the source for an appreciable vertical concentration gradient to exist, then the downward currents behind the building are more likely to produce an increase than a decrease of concentration. Large particles will certainly be deposited preferentially on the windward face of a building, but diffusion close to the lee side will be abnormal due to the local disturbance of flow.

## THE DISSIPATION OF FOG.

By PROFESSOR D. BRUNT, M.A.

*Received 3rd April, 1936.*

### 1. The Formation of Fog.

Fog is formed in air which is initially clear but damp, when the air is cooled to a temperature below its dew-point. The temperature of the air immediately above the surface of the earth is controlled by the temperature of the surface. The cooling necessary for the formation of fog may be produced in two ways; (a) by the loss of heat by long-wave radiation from the ground at night to a clear sky, or, (b) by the motion of warm damp air into a region where the surface of the earth is cold. Fogs formed by method (a) are known as "radiation fogs." Their formation requires a clear sky, and very light wind or calm. They do not form to the same extent on windy nights, as the turbulent mixing associated with strong winds distributes the loss of heat through so deep a layer that the dew-point is not attained.

Fogs of type (b) may form either over land or sea. At sea they form in such regions as the Great Banks of Newfoundland, where a warm damp current of air from the Gulf of Mexico flows over a sea surface cooled by the Labrador Current. Fogs form in precisely the same way over land, when, after a spell of cold weather during which the ground has become cold, a warm damp south-westerly current sets in. Such fogs may persist for days, with visibility limited to less than 100 metres. An example of such a fog occurred on Saturday, 15th February, 1936, persisting in places until the early morning of the 17th. After a week of fair and rather cold weather, a warm damp south-westerly current of air set in during the night of the 14th-15th.

## 2. Some Physical Facts.

Dense radiation fogs usually extend through a depth of 300 to 800 feet, while the temperature increases upward from the ground to the top of the fog by an amount which averages about  $5^{\circ}$  C. The amount of liquid water in a fog is from 3 to 8 per cent. of the amount of water present as vapour. Taking the mean value of about 5 per cent., we find that in a fog at  $5^{\circ}$  C. the amount of liquid water per cubic metre is 0.35 grammes.

Fogs formed by the motion of warm air over a cold surface have a mean motion of about 5 to 7 metres per second. True radiation fogs move so slowly that the usual meteorological instruments fail to record their motion. It is usually assumed that radiation fogs have a motion of the order of 1 metre per second, but accurate observations of this kind are lacking.

## 3. The Dissipation of Fogs.

For the sake of clarity we shall assume that the fog we have to dissipate is 100 metres deep, and moves at a rate of 1 metre per second, and that the clear space which it is desired to form shall be 100 metres wide, at least initially.

Any method of dissipating the fog which shall have any practical value must act rapidly through the whole depth of 100 metres, otherwise the cleared space will take the form of a tunnel sloping upward through the fog.

The methods of dissipating fog which have been put forward may be summarised under four heads, as follows :—

(a) The electrical method, which consists in subjecting the air to a very strong electrical field, preferably a brush discharge. There is no reason to suppose that this method could ever be effective in clearing such volumes of air as would be involved in any practical dissipation of fog.

(b) The mechanical method, which would bring down to the surface fog free air from above. The assumption that the removal of fog-laden air from the surface layers by suction would suffice to bring down from above clear air to replace it, does not appear justifiable, and the method has never been regarded a serious possibility.

(c) The thermal method of warming the fog until the fog-droplets are evaporated. This is considered in fuller detail below.

(d) The chemical method, which consists essentially in the removal of sufficient water vapour from the air which carries the fog droplets to ensure the subsequent evaporation of the droplets. This method is discussed more fully below.

## 4. The Thermal Method.

This method appears at first sight very promising, since the total amount of liquid water in a 100 metre cube is only 350 kilogrammes. To evaporate this will require about  $2 \times 10^8$  gramme calories, or say 8 therms, which, if taken from the domestic gas supply, would only cost about five shillings. In practice, it would be impossible to warm the whole depth, without bringing the vertical temperature distribution to the adiabatic, with temperature decreasing with height at the rate of  $1^{\circ}$  C. per 100 metres. To produce this temperature distribution would require another 36 therms, making a total of say 44 therms. It thus appears that the expenditure of 44 therms would suffice to clear a space

100 metres  $\times$  100 metres in a fog 100 metres deep. This space would slowly fill up again with fog as the result of the diffusion of foggy air laterally across the boundaries. If the fog had a general movement, the clear space would be carried away downwind, at the rate of 1 metre per second in the typical fog we specified above.

If the fog had a general motion of 1 metre per second, foggy air would cross the windward boundary of the space to be cleared at the rate of  $10^4$  (metre)<sup>3</sup> per second. If this air were heated as it crossed the boundary, sufficiently to clear it of fog-droplets by evaporation, heat would have to be expended at the rate of 0.44 therms per second, say 27 therms per minute. The air cleared of fog would move downwind at the rate of 1 metre per second, and the effect would be to produce a clear space which would be 100 metres wide at the windward edge, becoming narrower as it proceeded downwind. I estimate that in a light wind the width of the clear space would be about 50 metres at a distance of 600 metres from the windward edge, at which the heat is applied. Computing the cost on the basis of the use of gas, we find that the cost of forming such a clear space and maintaining it clear for a further ten minutes would be about £35, which is small by comparison with the aircraft which might be saved by landing in such a space.

The difficulty of applying this method consists in the fact that it is not possible *a priori* to work out the best way of applying the heat to the foggy air. No individual element of air must be heated to a temperature very far above that of its immediate surroundings, otherwise its buoyancy will carry it up through the fog so rapidly that its excess of heat is merely wasted. The burning of gas at the rate of 5400 cubic feet per minute, over a front of 100 metres, is not the simple problem it appears at first sight.

It would be easier to produce the necessary amount of heat by burning petrol, methylated spirit, or some other liquid, in troughs suitably distributed. Experimental work would have to be done to determine the best distribution of the sources of heat. Dr. C. F. Brooks, an American meteorologist, has described in his book entitled *Why the Weather*, a successful attempt to burn a hole in a fog over an aerodrome by burning two 50 gallon barrels of petrol poured on the aerodrome. When the fire had died down there appeared a hole in the fog, through which an aeroplane which had been waiting for it was able to land.

## 5. The Chemical Method.

The formation of fog requires an atmosphere containing suitable nuclei on which condensation can take place. The appearance of the fog is preceded by a fall of temperature, and an increase in the relative humidity, until a stage is reached at which condensation takes place upon the nuclei. The precise value of the relative humidity at which condensation begins depends on the nature of the nuclei, being lower for very hygroscopic nuclei than for the less hygroscopic.

Recent work carried out by Bowes and Houghton at the Massachusetts Institute of Technology has aimed at dissipating fog by destroying the equilibrium between the fog particles and the surrounding medium. In this work, a very hygroscopic substance, calcium chloride, is introduced into the foggy air, with a view to reducing the relative humidity of the air in which the water droplets are suspended below the limit at which condensation could begin on the original nuclei. This destroys the

equilibrium between the fog particles and the medium in which they are suspended, with the result that the fog particles evaporate.

In a laboratory experiment an artificial fog was prepared, and sprayed with small drops of saturated solution of calcium chloride. The results of this trial were so promising that it was considered worth trying out the method in a large scale experiment. Full details are not available of the large scale experiment, but it appears that it was carried out on a sea fog, a type of fog which drifts inland from the sea, but does not as a rule penetrate far inland. The saturated solution of calcium chloride was sprayed over a front of 100 feet from horizontal pipes set 30 feet above the ground, so that the drops of the solution fell through the fog, and in so doing scoured the air of its water vapour. The clear air formed by the evaporation of the fog droplets was carried forward by the wind, and the result was that a lane of clear air appeared in the fog, 100 feet wide and extending about 2000 feet downward. The initial visibility in the fog was 300 feet.

Little more than these bare facts have been published, and few details are available as to the visibility before, during, and after the spraying. Such observations are indispensable if we are to form a clear idea of the extent to which the apparent clearing was really due to the spraying of solution of calcium chloride. We are definitely not in a position to say that the one trial which has been reported in the Press was carried out under typical conditions.

There are at least three aspects of the problem of the dissipation of fog by chemical means which deserve consideration. In the first place, the nature of the nuclei on which the fog droplets are originally formed is of fundamental importance, since their nature determines the relative humidity at which condensation will begin, and therefore also determines the relative humidity to which it is necessary to dessicate the air between the fog droplets in order to produce evaporation of the droplets. It has usually been supposed that in a city fog the nuclei are more numerous and more highly hygroscopic than in a country fog, and that therefore the city fog is a dense cloud of very fine drops in an atmosphere whose relative humidity may be well below saturation, while the country fog consists of larger drops suspended in a medium whose relative humidity is about 100 per cent. It therefore appears safe to assume that if the relative humidity in a country or sea fog could be reduced to 90 per cent., the drops should evaporate, and the fog disappear. In a city fog, however, it would be necessary to reduce the relative humidity of the air to a much lower figure than 90 per cent., possibly to 70 per cent., in order to produce complete evaporation of the fog droplets.

In the second place, the choice of the most suitable substance for spraying the foggy air has to be considered. For the purpose of experiments on feasibility of fog dissipation calcium chloride is effective, though it has considerable disadvantages as a final solution of the problem. Calcium chloride, on account of its acid properties, is a highly corrosive substance, and it can hardly be regarded as a suitable substance to distribute widely over an aerodrome, or any other locality where machinery of any kind is exposed.

In the third place there is the question of the amount of the spray to be used, and the method of distribution. The amount of calcium chloride in the dry state required to reduce the relative humidity of the air in a space formed by a 100 metre cube from 100 per cent. to 90 per cent. is 140 kilogrammes. Or if, as in § 4 above, we consider the fog to

move at the rate of 1 metre per second, and distribute the salt at the windward edge of the space to be cleared in such a way as to clear the air of its fog as it crossed this edge, it is found that the dry chloride must be sprayed at the rate of 84 kilogrammes per minute. Using saturated solution of calcium chloride instead of the dry salt, 300 kilogrammes of saturated solution of the salt must be sprayed per minute.

The most serious problem which arises in this method of fog dispersion is the mechanical one of the distribution of the hygroscopic agent. At first sight, anhydrous calcium chloride appears to have a great advantage in that it reduces the weight of substance to be sprayed to the lowest possible value. But on account of its hygroscopic quality the dry salt is difficult to store, and probably difficult to distribute without its clogging any apparatus used in the process. The saturated solution has the advantage that no very special precautions are necessary in storing it, but for its distribution in an effective way it is necessary to determine the optimum size of drop, and to evolve a jet capable of emitting drops uniformly of that size.

It appears to be unlikely that any method can be evolved for the dissipation of a fog in which there is no definite wind, since the dissipation would involve the distribution of the chemical agent (or of heat if the thermal method were used) over the whole of the area to be cleared. When the fog has a definite motion in a direction which is determinable, it is only necessary to distribute the chemical agent (or heat) along the windward edge of the space to be cleared. This is still a difficult problem to solve, but it should be possible to get some definite result by experiment even if the method of distribution fell short of perfection.

Brief descriptions of the work done in America in developing the chemical method of fog dissipation are given in the following papers:—

(1) "A method for the local dissipation of natural fog," by E. L. Bowles and H. G. Houghton (Jnr.), *Miscellanea of the American Philosophical Society*, 16th September, 1935.

(2) In *Technology Review*, October, 1934, p. 20, *et seq.*, is given a semi-popular account of the work done by Houghton on the scattering of radiation in fog, and on fog dissipation.

### GENERAL DISCUSSION.

**Mr. C. F. Goodeve** (*London*) said: If this paper covers the present position of the practical dissipation of fogs, one is led to the conclusion that very little progress has been made. There seem to be many important questions still unanswered, only a few of which are indicated below.

In the calculation of the amount of gas required to evaporate the liquid droplets, no mention is made of the necessary temperature increase of the air. What effect on the cost would this have? The burning of gas or organic fuels produce water vapour and perhaps will do more harm than good? If a fog is dissipated, there is an increased loss of heat by radiation. Has any estimation of this loss been made? Have any calculations of the economic aspects of using calcium chloride been made? Could not fountains be used to avoid the erection of dangerous apparatus? Could the calcium chloride solution be cooled to increase its efficiency? If it were caught in a trough system, could not a cyclical process be operated? There are now standard methods for the economic control of humidity in factories by using refrigerating plant. Could not these methods be considered for the removal of fog?

**Dr. R. Lessing** (*London*) said that from experience with a coal cleaning process employing calcium chloride on a very large scale he could confirm that there was no danger of corrosion. He anticipated, however, that calcium chloride spraying on aerodromes would not be permissible as this electrolyte would coagulate the clay in the soil and inhibit the growth of grass, thus making the surface unsuitable for traffic on the ground.

**Mr. W. Barrett** (*Gerrard's Cross*) said: Heat could be applied to remove fog from aerodromes by buried networks supplied with low voltage current, as already done in horticulture. It seems also worth considering whether a cloud of drops of the order of  $60\mu$  radius could be laid down on the windward edge of the belt to be cleared, so as to bring down the fog particles. The cloud particles should be colder than the fog to avoid evaporation and subsequent condensation on fresh nuclei.

**Dr. B. W. Bradford** (*Billingham*) said: Attention may be drawn to work carried out in America on the dissipation of clouds by spraying with electrified sand from an aeroplane, in which excellent results were claimed. The economics of the method have not been investigated—it is probably expensive—but it might be applicable to special cases such as the dissipation of fog over estuaries, or of smoke screens or toxic smokes in warfare.

**Dr. R. Meldau** (*Berlin*) said: The idea of settling fog by dropping electrically-charged sand from aircraft has already been tried, but with the opposite effect.<sup>1</sup> Indeed, in this way Veraart brought about the formation of clouds and mists. Probably the Americans used one polarity and the Dutch the other; both made use of sands containing different size particles. Süring does not consider the Dutch method to be very hopeful. The experiments do not appear to have been followed up.

**Dr. N. Fuchs** (*Moscow*) (*communicated*): Experiments on rain-precipitation from the clouds by spraying calcium chloride on them from an airplane were recently made in U.S.S.R. For the most part, only structural changes in the clouds were observed after this operation, namely a clearing along the path of the airplane, the tearing of the cloud into several parts, etc. But in some cases a rainfall was actually obtained. At first the rain-drops were small, and their calcium chloride content high, but later on the drop-size increased and the rain was pure water.

**Professor D. Brunt** (*London*), in reply, said: My paper was not meant to be encyclopædic, as Mr. Goodeve would appear to suppose. A number of points not mentioned in the paper, including those raised by Mr. Goodeve, were considered, and omitted from the paper as irrelevant to the main question. The necessary temperature increase of the air involved in the evaporation of the fog is allowed for in the estimate of heat required, and is shown in the first paragraph of section 4 of my paper to be  $4\frac{1}{2}$  times the amount of heat required to evaporate the liquid water. The addition to the amount of water vapour present, involved in the use of liquid or gas fuel, is relatively small, and makes no essential difference to the estimates of cost which I gave. The increase in the loss of heat by radiation will not lead to any appreciable complication during an interval of time such as is aimed at in clearing fog. It has not been suggested that calcium chloride should be regarded at present as more than a suitable substance for experiments, and any calculations on the economic aspect of the choice of this particular compound appear a little previous. The suggestion of using fountains is quite impracticable. Drops of a size sufficiently small to present a reasonable amount of surface area to the air could not be sprayed up to heights such as are necessary for fog-clearing. The possibility of using a cyclical process such as Mr. Goodeve suggests might be considered at a later stage, but the first question is to decide whether the chemical method is at all feasible and effective. Methods involving the use of refrigerating plant, which may be effective in a closed vessel, or even inside a building, will not of necessity work in the open air.

<sup>1</sup> See A. Veraart, *Het kunstmatig verwekken van Regen*, N.V. Dr. Zuid-Holl. Boek-en Handelsdrukkerij, Gravenhage, 1930.

I now agree that I was mistaken in supposing that calcium chloride is corrosive, but this only removes one of several objections to the use of this substance.

Dr. Barrett's suggestion of using low voltage current to heat the air has never been tried, as far as I know. I cannot say how rapidly the heat from such a network would spread upward. A rapid diffusion of heat upward is not so necessary in horticulture, and the success of this method in horticulture does not of necessity mean that it would be effective in dissipating fog. Only an actual trial could determine the utility of the cloud of cold drops laid to windward of the area to be cleared.

The evidence as to the utility of electrified sand is so contradictory that it is impossible to assess its value.

The experiments described by Dr. Fuchs are puzzling, and it is far from obvious why the later stage of the experiments should give the precipitation of pure water.

## VARIATIONS IN THE ATMOSPHERIC DUST CONTENT DUE TO MICRO-ATMOSPHERIC INFLUENCES.

BY ROBERT MELDAU (*Charlottenburg*).

*Received 19th March, 1936, in German and translated by J. COLVIN.*

Holmes and his co-workers, in a report<sup>1</sup> by the American Committee of investigation on the smoke distribution from the Selby Copper Works in Montana (1915), first drew attention to the variable distribution of the smoke into regions. They marked "smoke routes" on a map (Table VI.) and established numerically that both the sulphurous acid content of the air and the arsenic and lead content of the soil were greatest at quite unexpected places in the region, namely, at 2.2 km. and 5.5 km. respectively from the chimney-stack. From the map, we may assume, without being able to particularise, that these phenomena are occasioned by a special configuration of the region, especially by locally restricted variations in the humidity (sea-shore, creeks).

If we insert numerically in the maps of the large towns, the measurements of the dust deposits, published by the Committee for Atmospheric Pollution, we find that the places of maximum deposition practically never coincide with the places of maximum industrial activity. The same conclusion is to be drawn both from the measurement of the annual dust deposit—as for example, in the town of Halle (Fig. 1)—and from the instantaneous measurements of Löbner in Leipzig<sup>2</sup> in 1935.

*Schaefererei Trotha* is situated in a slightly built-up area, *Barbarastrasse* separated from the industrial centre. The dust centres in Leipzig are irregularly distributed away from the station and factories.

If we compare the very valuable map on the characteristics of the poisonous Meuse valley fogs<sup>3</sup> with a geographical map, we must again

<sup>1</sup> Bull. 98, U.S. Bureau of Mines.

<sup>2</sup> Alfred Löbner, *Horizontale u. vertikale Staubverteilung in einer Grossstadt*, Leipzig, 1935.

<sup>3</sup> Batta, Firquet and Leqclerc, opposite p. 264 of their work.

conclude that it is not possible with any degree of certainty to explain, or even less to predict, where the zones of fog concentration must lie on geographical grounds and where fatalities are to be expected. Difficulties are encountered to a still greater extent if an attempt is made to explain why the fog concentration and the fatalities do not lie in the same zone, by assigning an essential part in precipitation to the land formation.

These and many other completely independent investigations, carried out moreover, for other purposes, seem to demand the following conclusions:—

(a) At certain places, the atmospheric pollution there arising is often disseminated irregularly into regions: wind direction and land formation do not always suffice to explain this irregularity.

(b) This irregularity is not merely a consequence of displacement of the smoke in bulk by the wind or of sedimentation during dispersal according to the size of particle, but is markedly variable.

(c) Thus fog and dust may first concentrate at unexpected places, sometimes quite remote from their place of origin.

The fine differences of temperature, humidity and of air currents (recently called microatmospheric) is an essential cause of this variation. Everyone who has carried out dust investigations has found that there exists not only in the open, but also in large factory rooms or assembly halls, a system of ascending and descending air currents and vortices, which, for example in closed halls, can bring about very stable zones of differentiated deposits.

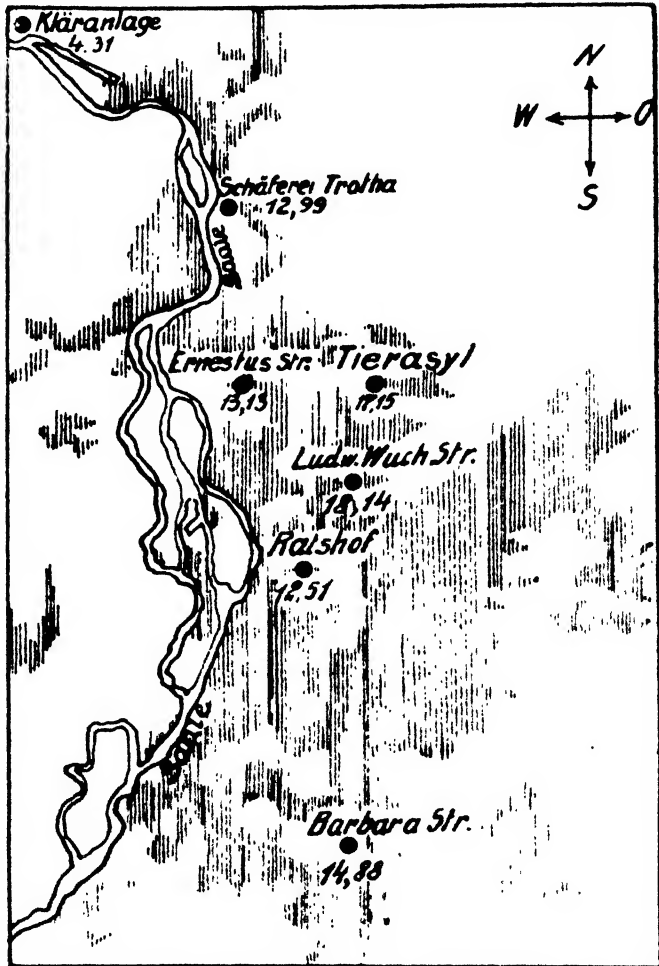

FIG. 1.—Dust deposit in Halle in 1931. (Relative values.)

FIG. 2.—Dust distribution and wind directions at a street crossing in Leipzig (Löbner). (Dust content in  $10^3$  particles per litre of air.)

Above machinery the warm air ascends, divides on reaching the ceiling and sinks, to be cooled at the external walls or windows.

The following examples may serve to show how finely distributed these microatmospheric currents are, and what differences in dust content they may effect.

Fig. 2 (Löbner<sup>3</sup>) shows how the dust content is distributed at a street crossing by a wind velocity of 2.8 metres per second. At the points (marked with crosses) 10 metres apart, on the right- and left-hand sides of a street, the dust content fell from 35 to 15 particles, i.e., by more than 100 per cent., as a result of the slight change in angle of the direction of the street.

Fig. 3 shows the air currents and the temperatures mapped out for a Berlin street. The differences in the temperature and in the currents which contribute to the variability of the dust content

FIG. 3.—Air-current and temperature map in a Berlin street running east-west, under the influence of a south wind of 2.7 metres/sec.

are clearly shown both at the ground and at higher levels.

<sup>3</sup> Cp. J. Grunow, *Der Luftaustausch der Grosstadt*, Z. V.D.I., 1936, 80, 71.

## GENERAL DISCUSSION.

**Dr. R. Meldau** (*Berlin*) (*communicated at the meeting*): It is worthy of note that, arising from the investigations upon which Firket has reported, the lines of equal dust content in open country do not coincide with the contour lines. I am indebted to Firket for showing me a diagram containing the measurements. It follows from the fact that such accretions and decrections of dust occur, that microanalysis of industrial dust should have exceptional significance, because it makes it possible to say whether a particular dust has originated from a particular source. As a result of extended experiments, I have demonstrated that such microanalysis can, in large measure, be utilised morphologically. The differentiation of the dusts may lie in their external shape, and surface condition, in their colour, reflectivity, or refractivity, or in their internal structure. These differences can readily be noted micrographically, especially if natural colours are used.<sup>1</sup> (The author then showed on the screen a small selection of his microphotographs.)

**Mr. W. Barrett** (*Gerrard's Cross*) said: Associated with wind, especially with gusty wind, are rapid variations of pressure. The air in a heap of dust responds to these and so the top particles are lifted into the system of eddies described by Dr. Meldau. It is probably for a reason of this nature that, under a falling barometer, dust is more readily lifted than at other times and this gives a physical explanation of the popular saying that blowing dust commonly foretells rain.

**Dr. R. Lessing** (*London*) called attention to the eddies produced in wind by buildings of even moderate height, and cited the case of an anemometer at a coastguard station on the Atlantic coast, the irregular working of which was traced to a cottage some distance away interfering with the streamline flow of the wind.

**Dr. R. Meldau** (*Berlin*), in reply, said: Settled dust is frequently lifted again. How settled dust may be lifted again from soil has been studied in the case of the sand-hills and of the ripple marks on sands, both in theory as in practice.

## THE ENERGY EFFICIENCY OF IONISATION IN ELECTRICAL PRECIPITATION.

BY C. A. MEEK AND R. WINSTANLEY LUNT.

*Received 27th March, 1936.*

### 1. Introduction.

In the phenomenon of electrical precipitation of dusts and mists it is possible to distinguish at least three main processes which lead ultimately to the precipitation of the particles:

- (i) The ionisation of the gas in which the dust or mist particles are suspended.
- (ii) The transfer of electric charge to dust or mist particles in collisions between these particles and electrons, positive ions,

and negative ions; the ions concerned being those derived from the molecules of the carrier gas.

- (iii) The motion of charged dust or mist particles due to the electric field between the electrodes.

In this paper we shall be mainly concerned with process (i). We shall consider firstly the general character of the process of ionisation of the carrier gas, particularly in its relation to the Townsend coefficient of ionisation, the electric field, and the pressure of the carrier gas. After noting the main characteristics of the type of discharge used in electrostatic precipitation, we shall then consider how far the conditions in such discharges depart from the optimum for effecting the ionisation of the carrier gas.

## 2. The Townsend Coefficient of Ionisation.

It was shown by Townsend<sup>1</sup> that if a constant current of electrons,  $i_0$ , be liberated from the surface of a (plane) metal electrode (for example, by allowing a beam of ultra-violet light to fall on it), and if a constant electric field be maintained between this electrode and some other plane electrode so that the electrons tend to move away from the surface at which they are liberated, then for any given pressure of gas in the space between the electrodes, the dependence of the total current flowing between the electrodes,  $i$ , and the distance between them,  $x$  cms., is given by

$$i = i_0 e^{\alpha x}, \quad (1)$$

where  $\alpha$  is a constant. Townsend interpreted this exponential growth of the current with the distance between the electrodes by supposing that the electrons leaving the cathode acquire sufficient energy from their motion in the field to enable them to ionise the gas molecules in collisions, the electrons formed simultaneously with the ions performing similar collisions. He showed that  $\alpha$  is a measure of the ability of the electrons to ionise, and is defined as the average number of ions generated (or of ionising collisions suffered) by an electron per cm. of its drift<sup>\*</sup> motion in the direction of the uniform electric field between the electrodes; he termed  $\alpha$  the coefficient of ionisation.

Numerous determinations, mainly by Townsend and his collaborators,<sup>2</sup> have shown that, in a given gas,  $\alpha p^{-1}$  is a function of the ratio  $Xp^{-1}$ , where  $X$  is the strength of the uniform field between the electrodes, and  $p$  the gas pressure; by convention  $X$  is expressed in volts cm.<sup>-1</sup>, and  $p$  in mm. Hg, so that  $Xp^{-1}$  is expressed in units of volts cm.<sup>-1</sup> mm. Hg.<sup>-1</sup>. An important point concerning these experiments to determine  $\alpha p^{-1}$  is that the current density was very small, being of the order of  $10^8$  electrons cm.<sup>-2</sup> sec.<sup>-1</sup> and that the pressure rarely exceeded 50 mm. Hg.

It is found that the dependence of  $\alpha p^{-1}$  on  $Xp^{-1}$  can be expressed to a close approximation by the empirical† expression over a wide

<sup>1</sup> Townsend, *Electricity in Gases*, Oxford, 1915, Chap. VIII.

<sup>\*</sup> The actual motion of the electrons is, of course, largely random; it is customary to speak of the component of the total motion in the direction of the electric field as the "drift" motion.

<sup>2</sup> Summarised in Knoll-Ollendorf-Rompe, *Gasentladungstabellen*, Leipzig, 1934.

† A theory of Townsend<sup>1</sup> which attempted to provide a theoretical basis for this expression is now recognised<sup>3</sup> to be based on untenable hypotheses.

<sup>3</sup> Cf., for example, Mierdel, *Handb. d. Experimental Physik*, vol. XIII., part 3.

range of  $Xp^{-1}$

$$\alpha p^{-1} = k_1 e^{-k_2 p X^{-1}}, \quad (2)$$

where  $k_1$  and  $k_2$  are constants characteristic of the gas concerned.

A quantity related to  $\alpha$  is the energy efficiency of ionisation,  $\eta$ ; this is defined as the average number of ions generated per electron-volt of energy supplied from some external source to maintain the discharge in which the ions are being produced. From the definition of  $\alpha$ , it follows that the average energy gained by an electron from the field,  $X$ , whilst it produces  $\alpha$  new ions, is simply  $X$  electron-volts, or

$$\eta = \alpha \cdot X^{-1} \quad (3)$$

Since

$$\alpha \cdot X^{-1} = (\alpha p^{-1}) \cdot (Xp^{-1})^{-1} \quad (4)$$

it follows that  $\eta$  is also a function of  $Xp^{-1}$ , and that values \* of  $\eta$  may at once be computed by means of (4) from the published data for  $\alpha p^{-1}$  and the corresponding values of  $Xp^{-1}$ . On substituting the approximate empirical expression for  $\alpha$  in (3) we find that  $\eta$  will be approximately represented by

$$\eta = k_1 \cdot p X^{-1} \cdot e^{-k_2 p X^{-1}} \quad (5)$$

From this it follows that a single maximum,  $\eta_{\max}$ , is to be anticipated for  $\eta$  considered as a function of  $Xp^{-1}$ , and that this maximum value will be attained when

$$Xp^{-1} = k_2 \quad (6)$$

The data for  $\eta$  in air derived from the published data for  $\alpha p^{-1}$  are shown in Fig. 1, from which it is seen that this quantity passes through a well-defined maximum,  $1.45 \times 10^{-2}$  ions per electron-volt for  $Xp^{-1} = 400$ .

Whilst little attention appears to have been paid previously <sup>4, 5</sup> to  $\eta$  or  $\alpha X^{-1}$ , it must be pointed out that long ago Townsend <sup>1</sup> recognised that the point of inflexion in the curves of  $\alpha p^{-1}$  as a function of  $Xp^{-1}$  provided the explanation for the Stoletow effect, and, of course, the existence of such a point of inflexion is formally identical with a maximum in  $\alpha X^{-1}$ . What does not appear to have been fully recognised until recently is that  $\alpha X^{-1}$  (or as we shall refer to it henceforth,  $\eta$ ) is an *energy efficiency* for the production of ions.†

Since  $\eta$ , the energy efficiency for the production of ions of the carrier gas, is clearly a matter of importance in any process of electrical precipitation, it is pertinent to enquire, firstly, how far this dependence of  $\eta$  on  $Xp^{-1}$  may be anticipated to remain valid in the corona discharges used in electrical precipitation, secondly, what are the values of  $Xp^{-1}$  in these discharges, and thirdly, how far the values of  $\eta$  for the usual corona conditions diverge from the maximum.

\* The relation to convert  $\eta$  ions per electron-volt to practical units,  $A$  gms. of ions per K.W.H., is

$$A = 37.4 \cdot M \cdot \eta,$$

where  $M$  is the molecular weight of the ion concerned.

<sup>7</sup> Von Engel and Steenbeck, *Elektrische Gasentladungen*, Berlin, 1932, p. 93.

### 3. The Dependence of $\eta$ on $Xp^{-1}$ in a Corona at Atmospheric Pressure.

It has already been mentioned that, in the experiments of the Townsend school to measure  $\alpha p^{-1}$ , the current density was extremely low, and the pressures of the order of a tenth of an atmosphere, or less. The first important application of these data to other conditions was Townsend's prediction of the sparking potential between parallel plates in gases at the same range of relatively low pressures.<sup>8</sup> The success attending this prediction indicates that the values of  $\alpha p^{-1}$  are still valid for the current density *immediately preceding the breakdown*; whilst such current densities must be considerably greater than those in the

FIG. 1.—The energy efficiency of ionisation in air,  $\eta$ .  
Curve 1, left hand and top scale; curve 2, right hand and bottom scale.

experiments to measure  $\alpha p^{-1}$ , they must be less than those in a discharge maintained solely by the potential between the electrodes\* (no measurements of the current density in the transition stage appear to have been made). In considering the experimental data for the sparking potential between parallel plates (and other shapes of conductors) at atmospheric pressure, Schumann,<sup>9</sup> by using a simplified form of the Townsend condition for breakdown,<sup>8</sup> came to the conclusion that the dependence of  $\alpha p^{-1}$  on  $Xp^{-1}$  was no longer represented by (2). He proposed several

\* Townsend, *op. cit.*, Chap. IX.

\* That is a "self-sustaining discharge"; in the experiments to measure  $\alpha p^{-1}$  the current is maintained by the photo-electrons ejected at the cathode and by the interelectrode field.

<sup>9</sup> Schumann, *Elektrische Durchbruchfeldstärke von Gasen*, Julius Springer, Berlin.

empirical formulæ, finally reaching the conclusion that the best of these was

$$\alpha = A \cdot X^{-2} \cdot \exp. (-B \cdot X^{-2}), \quad (7)$$

where  $A$  and  $B$  are positive constants, and  $X$  is the field strength \* in kV. cm.<sup>-1</sup>. Since the pressure is now constant (atmospheric) it does not appear in (7). Some idea of the empirical nature of this expression may be gained by noting that Schumann<sup>9</sup> selects values of  $A$  and  $B$  for a particular electrode configuration. The corresponding value of the energy efficiency, which we will denote by  $\eta_s$ , then follows as

$$\eta_s = 10^{-3} \alpha \cdot X^{-1} = 10^{-3} A \cdot X^{-3} \cdot \exp. (-B \cdot X^{-2}). \quad (8)$$

It is interesting to note that  $\eta_s$  also passes through a maximum as  $X$  (and hence  $Xp^{-1}$ , since  $p$  is now constant) progressively increases; by differentiating (8) it can easily be shown that  $\eta_{s, \max}$  occurs when  $X = (2B/3)^{0.5}$ , or

$$Xp^{-1} = (10^3/760)X. \quad (9)$$

The actual values of  $\eta_s$  cannot be computed from (8) because  $A$  is an unknown constant; we can, however, evaluate  $\eta_s/A$  which is proportional to  $\eta_s$ . By using Schumann's values for a wire-in-cylinder electrode configuration,  $B = 6300$ , it is found that  $\eta_{s, \max}$  occurs at  $X = 65$  kV. cm.<sup>-1</sup>, or  $Xp^{-1} = 85$ . It is a little difficult to estimate the weight that Schumann himself attaches to the values of  $\alpha$  given by (7), for, although he points out that these lead to a satisfactory (but empirical) interpretation of the phenomena of breakdown, he also points out that, for the above value of  $B$ , expression (7) predicts that  $\alpha$  itself will pass through a maximum for  $X = B^{0.5} = 79.5$  kV. cm.<sup>-1</sup>, and of the existence of this maximum he expresses considerable doubt.

The next developments come from the Rogowsky school where Paavola<sup>10</sup> showed that direct determinations of  $\alpha p^{-1}$  in air at atmospheric pressure by a modified form of the Townsend<sup>1</sup> technique are in substantial agreement with the values predicted from (2), using values for the constants  $k_1$ ,  $k_2$  derived from measurements of the Townsend school<sup>2</sup> at much lower pressures; these results were confirmed later by Masch.<sup>11</sup> It was then shown by Rogowsky that the use of these values of  $\alpha p^{-1}$  in a modified theory of breakdown led to predictions of the actual conditions of breakdown in good agreement with experiment.<sup>12</sup> If Rogowsky's theory be accepted, then his results show that the values of  $\alpha p^{-1}$  given by (2) are valid for atmospheric pressure and for current densities up to the value immediately preceding breakdown: again, although the absolute magnitude of this limiting current density is not known, it must be less than that in the discharge which follows. It then appears that Schumann's success in accounting for breakdown phenomena by using values of  $\alpha$  given by (7) and a simplified form of Townsend's condition for breakdown must be attributed to mutually compensating errors; it follows that the values of  $\eta_s$  given by (8) are open to considerable suspicion.

In the absence of any other relevant further experimental data, it is necessary to glance at the theory of the Townsend coefficient  $\alpha$  in

\* On account of the high field encountered in discharges at atmospheric pressure, it is customary to express these in kV. cm.<sup>-1</sup>, and for that we shall use the distinguishing symbol  $X$  where  $X = 10^3 x$ .

order to attempt a prediction of the continued validity of the dependence of  $\alpha p^{-1}$  on  $Xp^{-1}$  in the still greater current densities of an actual corona discharge.

#### 4. The Theory of the Townsend Coefficient $\alpha$ .

Emeleus, Lunt, and Meek<sup>13</sup> have recently shown that the theory of an electron swarm moving in a gas under the influence of a uniform electric field leads to the following expression for  $\alpha p^{-1}$ :—

$$\alpha p^{-1} = W^{-1} \cdot k \cdot M(\bar{V}), \quad (10)$$

where  $W$  is the average electron drift velocity in the direction of  $X$  and is known as a function of  $Xp^{-1}$  from the work of Townsend and his collaborators,<sup>8</sup>  $k$  a numerical constant  $= 1.86 \times 10^8$ , and

$$M(\bar{V}) = \int_0^\infty Q_i(V) \cdot V^{0.5} \cdot f(V) \cdot dV. \quad (11)$$

In (11)  $f(V)dV$  is the energy distribution function for the electrons in the swarm and must be a function,  $F(\bar{V})$ , of the average electron energy,  $\bar{V}$ ;  $\bar{V}$  is known from the work of the Townsend school<sup>14</sup> to be a function of  $Xp^{-1}$  for low current densities and gas pressures comparable to those used in the determination of  $\alpha p^{-1}$ . The expression  $Q_i(V)$ , the probability cross-section for ionisation by an electron of energy  $V$  electron-volts, is the quantity determining the probable number of ionising collisions made by an electron of energy  $V$  per cm. of its (actual \*) path through a gas. Since  $f(V)dV = F(\bar{V}) = F_1(Xp^{-1})$  by experiment, and since  $W = F_2(Xp^{-1})$  also by experiment, it follows from (10) and (11) that  $\alpha p^{-1}$  is predicted by this theory also to be a function of  $Xp^{-1}$ .

By using the data of Townsend<sup>14</sup> for the dependence of  $W$  and  $\bar{V}$  on  $Xp^{-1}$ , the data of Tate and Smith for  $Q_i(V)$ ,<sup>15</sup> and by making the assumption of a Maxwellian form † for  $f(V)dV$ , it is found that, for hydrogen and certain other molecular gases including air,‡ the values of  $\alpha p^{-1}$  (and therefore also of  $\eta$ ) calculated from (10) are in good agreement with experiment. This agreement between theory<sup>13</sup> and experiment is evidence that the only assumption involved, that of a Maxwellian electron energy distribution, must represent§ very closely the actual distribution in the experiments in which  $\alpha p^{-1}$ ,  $W$  and  $\bar{V}$  were determined as functions of  $Xp^{-1}$ . But the theoretically calculated values of  $\alpha p^{-1}$  are also in satisfactory agreement with the experimental values determined at atmospheric pressure,<sup>10, 11</sup> for which there are no corresponding data for the dependence of  $W$  and  $\bar{V}$  on  $Xp^{-1}$ . At this pressure there are therefore three assumptions ¶ involved in calculating  $\alpha p^{-1}$  from

<sup>13</sup> Emeléus, Lunt and Meek, *forthcoming paper in Proc. Roy. Soc.*

<sup>14</sup> Townsend, *The Motion of Electrons in Gases*, Oxford, 1925.

\* The velocity  $W$  is the component of the actual velocity in the direction of the field  $X$ .

<sup>15</sup> Tate and Smith, *Physic. Rev.*, 1932, **39**, 270.

† I.e.,  $f(V) \cdot dV = (27/2\pi)^{0.5} \cdot V^{0.5} \cdot e^{-1.5V/\bar{V}} \cdot dV$ .

‡ Since there are no  $Q_i(V)$  values for air, an approximate expression, based on that valid for other gases; this takes the form  $Q_i(V) = A \cdot (V - V_0)$  where  $V_0$  is now the "effective" ionisation potential<sup>3</sup> of air, 16.3 volts.

§ Although the assumption of this distribution effects the correlation between experiment and theory, there is no proof that it constitutes a unique solution, although this is highly probable for other reasons.<sup>13</sup>

¶ It is now necessary to assume, in addition to the Maxwellian nature of the distribution function, that the dependence of  $W$  and  $\bar{V}$  on  $Xp^{-1}$  is the same as that measured at much lower pressures.

(10) and (11): whilst it is, of course, possible that the observed agreement with experiment may be due to mutually compensating errors, it is more reasonable to conclude that the dependence of  $W$  and  $\bar{V}$  on  $Xp^{-1}$  at atmospheric pressure is sensibly the same as that observed at lower pressures, and that the electron energy distribution is still Maxwellian. This conclusion relates necessarily to the relatively low current densities for which  $\alpha p^{-1}$  was determined at atmospheric pressure.

It remains to consider whether this dependence of  $W$  and  $\bar{V}$  on  $Xp^{-1}$  and the distribution function may be anticipated to remain unchanged in the *considerably higher* current densities of corona discharges at atmospheric pressure. The early experiments of Wilson<sup>28</sup> indicate that the values of  $W$  in positive column discharges in air at low pressure are of the same order of magnitude as those determined for much lower current densities. Whilst there is no evidence for discharges at atmospheric pressure, a related case with which comparisons may be made is that of the formation at atmospheric pressure of ozone from oxygen in ozoniser discharges; this form of discharge is essentially a capacity limited corona. Lunt and Meek<sup>16</sup> have calculated by expressions formally similar \* to (10) and (11) the energy efficiency for the formation of ozone from oxygen as a function of  $Xp^{-1}$  in fair agreement with experiment. In performing these calculations it has been assumed, in addition to the existence of a Maxwellian electron energy distribution, that the dependence of  $W$  and  $\bar{V}$  on  $Xp^{-1}$  *for oxygen* at atmospheric pressure is the same as that measured<sup>14</sup> at much lower pressures. Whilst this result might again be due to mutually compensating errors, it suggests strongly that the assumptions involved are correct. If this conclusion be accepted then it is reasonable to infer that it may also be anticipated that, also *in the case of air* in a discharge at atmospheric pressure, the electron energy distribution is sensibly Maxwellian, and the dependence of  $W$  and  $\bar{V}$  on  $Xp^{-1}$  is sensibly the same as that measured<sup>14</sup> at much lower pressures. It then follows that the dependence of  $\eta$  on  $Xp^{-1}$  given in Fig. 1 may also be anticipated to remain valid in the conditions of atmospheric corona.

There is ample experimental evidence from probe data that, discharges at low pressure the electron energy is frequently Maxwellian,<sup>17</sup> at least to a close approximation; and Druyvesteyn has recently pointed out in a theoretical investigation of the distribution function<sup>18</sup> that, on account of the interaction between ions and electrons, the distribution for the high current densities of a self-maintained discharge (of which corona is one example) must approximate closely to the Maxwellian.

Summarising this discussion of the actual values of  $\alpha p^{-1}$  and  $\eta$  at atmospheric pressure for low current densities, and their continued validity in a corona discharge, we see, firstly, that the direct determinations of Paavola<sup>10</sup> and Masch<sup>11</sup> for low current densities indicate that no great reliance can be placed on the values given by the empirical expression of Schumann. Secondly, that although there is no direct evidence for the continued validity of these values in corona discharges, there are many lines of argument which indicate that this is probably the case.

### 5. The Field in a Corona Discharge.

Whilst a complete theory of the mechanism of corona discharges is still lacking, it is generally accepted that ionisation by electron impact is confined to a luminous zone, the corona itself, close to one (or both in the case of a parallel wire system) electrode. It is therefore in this zone of the discharge that it is pertinent to the practice of electrical precipitation to consider the values of  $Xp^{-1}$  and the corresponding values of the energy efficiency for ionisation of the gas,  $\eta$ . For simplicity we shall confine our attention to the "wire-in-cylinder" type of electrode arrangement, and, in particular, consider the case closely related to current practice, a 1/16-inches diam. wire centrally placed with respect to a tube of 7 inch diam.; the radius of the wire,  $r$ , is then 0.080 cm., that of the cylinder,  $R$ , 8.9 cm., and the spacing between the electrodes,  $a$ , 8.82 cm. In order to illustrate certain theoretical predictions we shall also consider the case of a larger wire diameter,  $r = 0.200$  mm., in the same sized outer cylinder so that the value of  $a$  is now 8.70 cm.

Unfortunately, there appear to have been no direct determinations of the field between concentric cylinders for continuous current corona discharges since those of Booth<sup>19</sup> in 1917; and from the small scale diagrams reproduced in his paper it is impossible to estimate the field in the region of the actual corona, the diameter of which can be estimated from independent data. It is therefore necessary to approach the problem from the theoretical side, which, as has been mentioned, is far from being completely developed.

The earliest theory of the current-voltage relationship in corona discharges is due to Townsend.<sup>20</sup> In this it was assumed (amongst other things) that the field at the outer edge \* of the corona,  $X_{c,0}$ , was equal to limiting critical field for breakdown at large electrode spacings between conductors of small curvature, about 30 kV. cm.<sup>-1</sup> in air at atmospheric pressure; it was also assumed that the ionisation in the corona was determined by the mean field in the corona which was itself assumed to be given by  $0.5(X_c + 30)$ , where  $X_c$  is the critical field at the surface of the wire necessary to produce corona. The assumption that  $X_{c,0} = 30$  kV. cm.<sup>-1</sup> has also been used later by Peek<sup>21</sup> in attempting to provide an explanation for the dependence of the corona diameter on the applied voltage. In a recent investigation Prinz<sup>22</sup> has pointed out that the Townsend theory (together with several others) fails to predict the experimentally observed relationship between the applied potential and the power absorbed by the discharge, and that this failure is attributable, in part, to the neglect in these theories of the effects due to the field in the corona itself, and to the assumption that  $X_{c,0} = 30$  kV. cm.<sup>-1</sup>. Prinz then develops a modified theory of corona which takes account of the field in the corona; the great merit of this theory is that it predicts the observed potential-power relationship despite the fact that, as Prinz himself admits, it is to some extent empirical. Not merely does this theory enable calcula-

<sup>19</sup> Booth, *Physic. Rev.*, 1917, 10, 266.

<sup>20</sup> Townsend, *op. cit.*, Chap. X.

\* The symbol  $X$  will be used to denote field strengths expressed in kV. cm.<sup>-1</sup>, thus distinguishing them from  $X$  which refers to volts<sup>-1</sup> cm.<sup>-1</sup>.

<sup>21</sup> Peek, *Dielectric Phenomena in High Voltage Engineering*, 2nd edition, New York, 1932.

<sup>22</sup> Prinz, *Die Gleichspannungskorona*, Dr. Ing. thesis, München, 1934.

tions to be made of the field in the corona,  $\mathbf{X}_x$ , as a function of the radial distance  $x$ , but it also leads to the conclusion that  $\mathbf{X}_{c,0}$  is less than 30 kV. cm.<sup>-1</sup> by an amount depending on the geometry of the electrode system. This latter conclusion is of particular importance for electrical precipitation, because, as may be seen from Fig. 1, the lower the value of  $\mathbf{X}_x$  (and therefore also of  $X_x \cdot p^{-1}$ ) the lower is the value of  $\eta$ .

We shall now consider the application of Prinz's theory to the particular cases mentioned previously. The first relationship required is that of the dependence of the corona radius,  $x_0$ , on the applied potential  $V$  kV. For this there are no completely satisfactory data, due mainly to the fact that this radius is difficult to define; we shall rely here on the photographic determinations with quartz lenses by Whitehead<sup>23</sup> who found that for values of  $V$  exceeding the critical value for the commencement of corona,  $V_c$ , by more than a small amount (of the order of 5 kV.) the relation is

$$x_0 = r + K \cdot (V - V_c), \quad (12)$$

where  $K$  is a constant depending on the geometry of the system. The case investigated by Whitehead approximating most closely to that we are now considering was for  $r = 0.1165$  cm. and  $R = 9.3$  cm.; from his data the value found for  $K$  is 0.035. Prinz adopts the value  $K = 0.5$  cm. kV.<sup>-1</sup> which is obviously impossibly high, but from the data given in his Fig. 57 it appears that the value corresponding to the other conditions stated on that Fig. is  $K = 0.0565$  cm. kV.<sup>-1</sup>, but whether this is an experimental value is not clear. We shall adopt the experimental value  $K = 0.035$ , and consider the case for a relatively large corona radius  $x_0 = 1$  cm. For the values of  $r$  and  $R$  selected, the values of  $V_c$ , found from the standard (experimental) expressions,<sup>21, 22</sup> are approximately 25 kV. and 42 kV. respectively.

According to Prinz's theory,<sup>22</sup> the field at the outer edge of the corona,  $\mathbf{X}_{c,0}$ , is given by

$$\mathbf{X}_{c,0} = x_0^{-1} V_c + (x_0 - r)/K \cdot \frac{\beta - 1}{\beta(\beta - 2)} \\ \times \left[ 1 - \sqrt{1 - \frac{\beta - 2}{(p-1)^2} \beta \left\{ \frac{1.32}{1 + \frac{x_0 - r}{KV_c}} - 0.32 \right\}} \right] \quad (13)$$

where, for the case of concentric cylinders,  $\beta = \log_e R/r$ . After performing the calculations, it is found that for  $r = 0.080$  and 0.200 mm. the values of  $\mathbf{X}_{c,0}$  are, respectively, 2.3 and 7.3 kV. cm.<sup>-1</sup>; the corresponding values for the potential across the electrodes according to (12) are  $V = 50$  and 65 kV. respectively.

It must be pointed out that these values of  $\mathbf{X}_{c,0}$  are surprisingly low, and until direct confirmatory evidence is available, we believe that they must be accepted with some caution. Since the wire electrode is negative, the corona itself may be regarded as a glow discharge in which, due to the high pressure, the negative zones have contracted to microscopic dimensions close to the wire, so that the main bulk of the corona will approximate to a positive column. There are unfortunately few data for positive column discharges in air, but Wilson<sup>24</sup>

<sup>23</sup> Whitehead, *Proc. A.I.E.E.*, 1912, **31**, 839.

<sup>24</sup> Wilson, *Proc. Camb. Phil. Soc.*, 1902, **11**, 249, 391.

in 1902 showed that at low pressures, and for current densities comparable to those in corona at atmospheric pressure

$$Xp^{-1} = 35 \cdot p^{-0.5} \quad (14)$$

If we assume that this relation is still valid at atmospheric pressure, the value of  $Xp^{-1}$  is 1.28; this result would then signify that luminous discharges would be expected to occur in air at atmospheric pressure for this value of  $Xp^{-1}$ . It will be noticed that this value is considerably below the values of  $Xp^{-1}$  corresponding to the values of  $\mathbf{X}_{c,0}$  derived from the application of Prinz's theory, the relation between  $Xp^{-1}$  and  $\mathbf{X}_{c,0}$  being given by

$$Xp^{-1} = (10^3/760)\mathbf{X}_{c,0} \quad (15)$$

We may therefore find in these results of Wilson some provisional justification for accepting the low values of  $\mathbf{X}_{c,0}$  predicted by Prinz's theory.

In order to calculate the energy efficiency of ionisation in the corona we require to know, firstly, the values of  $Xp^{-1}$  at the radial distance  $x$ ; these follow from (15) when  $\mathbf{X}_{c,0}$  is replaced by the  $\mathbf{X}_x$ , the field at the radial distance  $x$ , which, from Prinz's theory, is given by

$$\mathbf{X}_x = x^{-1} \cdot x_0 \cdot \mathbf{X}_{c,0} \quad (16)$$

It is found that resulting values of  $Xp^{-1}$  inside the corona lie partly below the range in which  $\alpha p^{-1}$  (and thence  $\eta$ ) has been measured,  $Xp^{-1} \geq 31$ . For the values of  $Xp^{-1} < 31$  the data of Masch do not suggest any obvious method of extrapolation; we have therefore made the somewhat arbitrary assumption that  $\eta$  has the constant value of  $0.05 \cdot 10^{-2}$  corresponding to the measurements at  $Xp^{-1} = 31$ . Some justification for this procedure is afforded by the work of Emcléus, Lunt and Meek,<sup>13</sup> who have concluded that at very low values of  $Xp^{-1}$  the electron energy distribution varies in such a way that the diminution of  $\eta$  as  $Xp^{-1}$  diminishes is not nearly so rapid as that predicted by (10) for a Maxwellian distribution. In any case, the error introduced probably leads to high rather than low values of  $\eta$  for  $Xp^{-1}$  less than 31. For higher values of  $Xp^{-1}$ ,  $\eta$  has been derived from the data of Masch,<sup>12</sup> Fig. 1.

Since  $Xp^{-1}$  varies in the corona itself, the quantity of interest to evaluate is the average value of the energy efficiency of ionisation in the corona,  $\bar{\eta}$ . From the definition of  $\eta$  it follows that the rate of generation of ions at the radial distance  $x$  is given by the product of  $\eta$  and the rate at which energy is supplied to maintain the corona at this radial distance.

If  $I$  is the current in  $\mu A$  per cm. length of the wire-in-cylinder system, then the energy input to the corona per cm. length,  $P_c$ , is given by

$$P_c = 6.3 \cdot 10^{15} \cdot I \int_r^{x_0} \mathbf{X}_x \cdot dx \text{ electron-volts sec.}^{-1},$$

or, by (16),

$$\begin{aligned} P_c &= 6.3 \times 10^{15} \cdot I \cdot \mathbf{X}_{c,0} \cdot x_0 \int_r^{x_0} x^{-1} \cdot dx \\ &= 6.3 \times 10^{15} \cdot I \cdot \mathbf{X}_{c,0} \cdot \log_e x_0/r. \end{aligned} \quad (17)$$

Similarly, the total ionisation per cm. length,  $N_i$  ions sec.<sup>-1</sup>, is given by

$$N_i = 6.3 \times 10^{15} \cdot x_0 \cdot I \cdot \mathbf{X}_{c,0} \int_r^{x_0} \eta_x \cdot x^{-1} \cdot dx, \quad (18)$$

where  $\eta_x$  is the value of  $\eta$  at the radial distance  $x$ . From these expressions the average value of  $\eta$  may be found, and is given by

$$\bar{\eta} = N_i \cdot P_c^{-1} = \frac{\int_r^{x_0} \eta_x x^{-1} dx}{\log_e (x_0/r^{-1})} \quad (19)$$

The values of the integral in (16) must be found by quadrature. After evaluating this integral and  $P_c$  for the two values of  $r$  under consideration, we find for  $r = 0.080$  and  $0.200$  cm., respectively,  $\bar{\eta} = 5.6 \times 10^{-5}$  and  $1.22 \times 10^{-4}$ . This shows that  $\bar{\eta}$  is considerably higher for the thicker wire, but is still only 1.2 per cent. of the maximum value,  $1.45 \times 10^{-2}$  (Fig. 1).

It must, of course, be pointed out that this gain in the average value,  $\bar{\eta}$ , by using a thicker wire is achieved at the expense of a higher operating potential. It is therefore pertinent to consider next the overall energy efficiency,  $\bar{\eta}_0$ , referred to the total energy supplied to maintain the corona,  $P_t$ . Per cm. length of wire,  $P_t$  is given by

$$P_t = 6.3 \times 10^{15} IV \text{ electron-volts sec.}^{-1}.$$

Hence from (17) and (19) the overall energy efficiency of ionisation,  $\bar{\eta}_0$ , is given by

$$\bar{\eta}_0 = \bar{\eta} \cdot P_c \cdot P_t^{-1}; \quad (19)$$

the values of  $\bar{\eta}_0$  derived from (19) for  $r = 0.080$  and  $0.200$  cm. are, respectively,  $6.55 \times 10^{-6}$  and  $2.20 \times 10^{-5}$ . These results show that despite the increased operating voltage, there is still a considerable increase in overall energy efficiency of ionisation to be gained by using wire of larger diameter.

Summarising this application of Prinz's theory to the conditions of electrical precipitation, the most striking result is the prediction of very low values of the (ionising) field in the corona itself. The authors therefore believe that direct experimental determination of the field in corona would be of considerable importance, for the fact that Prinz's theory correctly predicts the dependence of the direct current corona loss on the voltage, and geometry of the system, cannot of itself be regarded as complete proof of the validity of this admittedly<sup>22</sup> semi-empirical theory. The values of the average energy efficiency corresponding to these low corona fields are also extremely low compared with the predicted maximum; the calculations for central wires of different diameters indicates that a considerable gain of efficiency of ionisation may be achieved by the use of large central wires.

## 6. The Effect of Dust and Mist on $\eta$ .

The calculations made in the preceding section relate to air alone; it is next necessary to enquire how far the conclusions reached there might be modified by the dust or mist present in actual precipitating conditions. In their recent summary, Mierdel and Seeliger<sup>25</sup> have pointed out that the presence of dust or mist lowers the critical corona voltage and increases the corona current for a given applied voltage. These results suggest that, other things being equal, the presence of dust or mist tends to lower the field in the corona and therefore also the energy efficiency of ionisation. As in the case of dust-free air discussed

<sup>25</sup> Mierdel and Seeliger, *Arch. f. Elektrotechnik*, 1935, **29**, 149.

in the previous section, no certain conclusions can be drawn until direct determinations of the field in the corona have been made when dust or mist is present.

### Summary.

Reasons have been given for believing that the value of the energy efficiency of ionisation in air at atmospheric pressure determined at low current densities are valid in the higher current densities of corona discharges.

The recent theory of Prinz has been applied to calculate the field strength in corona for conditions approximating to those found in the practice of electrical precipitation. This theory predicts that the field strength will increase with the wire diameter.

From the values of the field strength derived from the application of Prinz's theory the overall energy efficiency of ionisation has been calculated. These are found to lie far below the maximum value.

This application of Prinz's theory has revealed that further experimental work is desirable to determine the dependence of corona size on the electrical and geometric factors, and to determine the field in the corona itself.

## THE PHYSICAL BASIS OF ELECTRICAL GAS PURIFICATION.

BY G. MIERDEL AND R. SEELIGER.

(Received in German, 11th May, 1936; and translated by R. W. Lunt.)

It is well known that in principle electrical gas purification consists in subjecting the mixture of gas and dust to a unidirectional electric field in which an electric discharge in the form of a corona is taking place. The dust particles become charged in the latter, so that they move in the field towards one of the two electrodes where they are deposited for the most part as a firmly coherent layer. In principle, the charging and precipitation can take place in separate units, the gas stream flowing from one to the other, an arrangement which can be advantageous in many cases. In practice, however, almost without exception the two processes take place in the same apparatus, and this essentially takes one of two forms, wire-in-cylinder, or wire-and-plate.

### (1) The Charging of Dust Particles in the Corona Discharge.

In gases at high pressure, which conditions alone are now relevant, it is possible to distinguish two zones in a corona discharge: there is a narrow, luminous zone in the neighbourhood of the wire electrode, the corona itself, and a completely non-luminous region which extends from the corona to the outer electrode. This visual difference between the two zones can be accounted for theoretically. In the corona there is a field distorted by space charge maintaining the discharge in a steady

state, and in which the necessary charged particles of the same sign as the wire are generated by electron collisions ("electron avalanche"). These charged particles are carried to the other electrode by the field in the non-luminous or "transport" zone. On account of the relatively small volume of the corona, the transport zone is practically the only region which is effective in charging the dust particles; a more exhaustive examination of the processes occurring in the corona is therefore only of secondary interest for the theory of charging the dust.<sup>1</sup>

It will suffice to consider here a negatively charged wire, and therefore negatively charged carriers, in the transport zone, for these are the only conditions found in practice; that is why *ceteris paribus*, the current for negative corona is somewhat greater than for positive, and, more important still, the breakdown potential, which sets an upper limit to the operating electrode potential, is also appreciably greater for negative corona.<sup>2</sup> Under these conditions, negatively charged carriers (molecular ions) leave the corona and wander towards the anode, their motion being determined by their mobility and the field in the transport zone. The concentration of these carriers varies from case to case, and from place to place, depending on the field; for the usual conditions found in practice, an average value is  $10^6 \text{ cm.}^{-3}$ . The dust particles present thus exist in an atmosphere of (uncharged) gas, admixed with a negative ion gas, the latter having an extremely small partial pressure (about  $10^{-11} \text{ mm. Hg}$ ). From this standpoint, the charging of the dust particles can at once be understood. The ion gas naturally takes part in the general thermal motion, and its temperature is but slightly higher than that of the (uncharged) gas. The dust particles suffer collisions with ions about  $10^{11}$  times less frequently than with neutral molecules, and they must gradually become more and more strongly charged negatively, because the ions give up their charge on reaching the surface of a dust particle, and because there is no mechanism available by which the dust particles can acquire a compensating positive charge. This charging takes place with a gradually diminishing velocity because of the corresponding increase in the force exerted on an approaching ion. The finite time of transit of a dust particle through the ion atmosphere sets a limit to the charge which may be acquired, which, as experiment shows,<sup>3</sup> is proportional to the radius,  $r$ , of the particles which are assumed to be spherical; for normal operating conditions the number of elementary charges,  $q$ , acquired by a dust particle, is given by  $q = 2 \cdot 10^6 \cdot r$ .

Apart from this purely kinetic treatment of the mechanism of charging, there is also the possibility that charging may occur in a region where there is a much higher field. In fact, such a field, under certain conditions, may be able to effect the further charging of a particle when the forces exerted by it on a colliding ion have become so large that, on account of its thermal motion alone, practically no further transfer of charge from ions is possible. The limiting charge,  $Q_s$ , which may be acquired by a particle under the influence of an external field,  $E$ , can be derived by considering the equilibrium between the forces at the surface of a particle, and the distortion of the (initially) homogeneous field by polarised dust particles, assumed spherical as before. If the dielectric constant of the particles is  $D$ , then  $Q_s$  in elementary units is given by

$$Q_s = e^{-1} [1 + 2(D - 1)/(D + 2)] E \cdot r^2,$$

where  $e$  is the electronic charge.

For the conditions obtaining in practice ( $E = \text{about } 3 \text{ kV. cm.}^{-1}$ ), and for particles greater than about  $1\mu$  diameter, it can then be seen from the above expression that the limiting value of the charge which may be acquired under the influence of the field may exceed that arising from gas kinetic effects alone, *i.e.* that above this particle size the limiting charge increases as the square of the particle radius. This relationship has been frequently verified by experiment, for example, recently by Fuchs, Petrijanoff and Rotzeig.<sup>4</sup>

The question now remains as to whether the time of transit of a particle under the conditions obtaining in practice is adequate to allow the limiting charge to be acquired. Pauthenier and Moreau-Hanot<sup>5</sup> have given the following expression for the growth of the charge with time:—

$$Q = Q_0(\pi \cdot b \cdot n \cdot e \cdot t)/(1 + \pi \cdot b \cdot n \cdot e \cdot t),$$

where  $b$  is the mobility of the ions ( $b = 600 \text{ e.s.u.}$ ),  $n$  the carrier concentration ( $10^8 \text{ cm.}^{-3}$ ), and  $e$  the electronic charge. On inserting these values in the above expression, it is found that a transit time of 0.1 sec. is necessary for 90 per cent. of the limiting charge to be acquired. For a gas velocity of  $2 \text{ m. sec.}^{-1}$ , which is an average value for industrial practice, it is then seen that it would be necessary for the particle to traverse only 20 cm. in order to be charged; this distance is negligible compared with the several meters of effective precipitator length usually employed.

## (2) The Drift and Precipitation of Dust Particles.

Having derived the charge on the dust particles, it is now possible to discuss the velocity with which they drift to the anode, or precipitation electrode. Assuming, as before, spherical particles, the drift velocity,  $w$ , for particles of present interest (*i.e.* from  $0.1 - 10\mu$  diam.<sup>6</sup>) may be derived from Stokes' law, or

$$w = E \cdot e \cdot Q/(6\pi \cdot \eta \cdot r),$$

where  $\eta$  denotes the viscosity of the gas. The particles drift with this velocity  $w$  towards the anode where they remain and become precipitated. Although there is this loss of particles at the anode, the concentration of particles throughout the gas is maintained uniform by the turbulence of the streaming gas and also by the eddies due to the electric wind; it can then be seen that the concentration must fall exponentially along the gas stream through the precipitator. This exponential relationship between the concentration and the time of transit, or the length of the precipitator, was demonstrated by Anderson and Horne in America at the time when the technical development of electrical gas purification was beginning. More recently, Deutsch<sup>7</sup> developed the complete expression relating the degree of purification  $\zeta$ , defined as the ratio of the residual to initial dust content, to the drift velocity  $w$ , the mean gas velocity  $v$ , and the precipitator dimensions (length  $L$ , and electrode separation  $s$ ). This expression takes the following forms:—

$$\begin{aligned} \text{for wire-in-cylinder systems } \zeta &= 1 - \exp. \{-2 \cdot w \cdot L/(s \cdot v)\}, \\ \text{for wire-and-plate systems } \zeta &= 1 - \exp. \{-w \cdot L/(s \cdot v)\}. \end{aligned}$$

It is thus possible to calculate the dimensions of a precipitator for a specified  $\zeta$  from given data for the dust laden gas. Alternatively, the correctness of the above expressions can be tested, for example, from

measurements of the variation of  $\zeta$  with  $v$ , and from these  $w$  could be derived and then compared with the theoretically calculated value.<sup>8</sup>

The field strength in a precipitator,  $E$ , is mainly determined by the space charge associated with the drift of unipolar carriers, and a knowledge of  $E$  is necessary to calculate  $w$  and  $Q$ . For a wire-in-cylinder system Townsend has derived an expression from which it follows that  $E$  is simply determined by the current density and  $b$ , except in regions in the immediate neighbourhood of the wire; this expression is  $E = (2i/b)^{0.5}$  where  $i$  is the current per cm. of precipitator length. For the conditions obtaining in practice  $i$  may be taken as 0.01 ma. (or  $3 \cdot 10^4$  e.s.u.) cm.<sup>-1</sup> and, using as before,  $b = 600$  e.s.u., it is then found that  $E = 10$  e.s.u., or 3000 volt cm.<sup>-1</sup>. The derivation of  $E$  for a wire-and-plate system is beset with considerable difficulties, and it is necessary to assume that, to a first approximation, the values of  $E$  will not differ appreciably from those in a wire-in-cylinder system. On introducing these calculated values of  $E$  into the expressions given previously for the charging and the mobility, it may be shown that small particles of diameter less than  $1\mu$  drift with a velocity of a few cms. sec.<sup>-1</sup> practically independent of their diameter, and that, on the other hand, larger particles drift with a velocity proportional to their diameter, for example, about 25 cm. sec.<sup>-1</sup> for a diameter of  $10\mu$ .

The very good agreement between calculation and experiment affords evidence that there is no process contributing appreciably to the removal of dust in electrical precipitators other than those already mentioned. In particular, contrary to earlier opinion,<sup>9</sup> the electric wind does not effect the directed transport of dust particles to the precipitation electrode, a conclusion that would be at variance with the continuity of the gas stream.<sup>10</sup>

### (3) The Influence of Dust on the Electrical Conditions.

We will now turn to consider the effect of dust before and after precipitation on the electrical conditions in a precipitator; this is a matter of practical importance.

Uncharged dust has no effect on the corona discharge. The effect of charging the dust is to introduce a large number of carriers of greatly diminished mobility, and consequently a space charge. Whilst the fraction of the total current carried by the (charged) dust particles is little more than 1 per cent. under normal conditions, the space charge, being equivalent to the introduction of a negatively charged grid, has a considerable effect in diminishing the total current. It can be shown that the presence of this space charge necessitates a modification of the Townsend expression for the current-potential relationship in a wire-in-cylinder system,  $i = V(V - V_c)$ , in such a way that  $V_c$  is increased, the amount being numerically equal to the space charge per cm. length of the system;<sup>11</sup> an experimental verification of this deduction has been described by one of us.<sup>12</sup> In practice, the increase in  $V_c$  may amount to several kV., and leads to a diminution of the current, which latter effect may, however, be avoided by suitably increasing the electrode potential,  $V$ .

The effect on the discharge of the deposition on the anode of coherent layers of precipitated dust is much more complicated, and also introduces serious practical difficulties. The effect is mainly dependent on the structure and moisture content of the precipitated dust, and may,

therefore, take many forms. A systematic examination of the available technical data, together with laboratory experiments, has led at least to a qualitative elucidation of the principal phenomena.<sup>13</sup> A characteristic effect is the appearance of ionisation on the precipitated dust layer: this can lead either to a stabilisation of the discharge, or to a disruptive discharge, sparking. In the former case, there is an increase in the current and a decrease in the efficiency of precipitation; in the latter case, the operating potential is diminished whenever spark-over due to the dust occurs, and consequently the efficiency of precipitation is also decreased.

The theoretical explanation of the foregoing effects arising from the precipitated dust layer on the anode may be expressed in the following terms. In the case of a layer of low ohmic conductivity, from dry dust, the potential across the layer due to the passage of the total current would amount to a considerable fraction of the electrode potential; the current therefore tends to flow through cracks in the dust layer in which ionisation of the gas has occurred. If the dust layer is sufficiently homogeneous for the cracks, and hence the alternative current paths, to be uniformly distributed throughout the layer, the stabilising effect previously mentioned is attained. On the other hand, if the current flow through the layer is highly localised, then the resulting high current densities at these points give rise to conditions favouring the development of sparking.

Various devices are employed in practice in order to minimise these difficulties. The resistivity of the (precipitated) dust may be very greatly diminished by the introduction of moisture, either before or after precipitation. Further, by suitable choice of the geometry of the precipitation electrode, the formation of thick layers can be avoided, the dust being collected through slits or holes ("pocket electrodes," "high power electrodes"). The wave form of the electrode potential has also an influence of behaviour of a precipitator. Whilst a d.c. potential is naturally most effective for a speedy charging of the dust (its maximum value being set by the breakdown potential for the system), it has been found sometimes to be advantageous to super-impose a 50-cycle wave on the usual d.c. potential; this is especially the case for dusts of low conductivity, and the effect is attributed to the possibility that this procedure affords for the "dust condenser" to discharge in the intervals of zero current, and thus avoid the building up of potentials which might otherwise lead to breakdown.

In conclusion, it may be remarked that the essential points of the theory of the physical processes involved in electrical precipitation are understood, and that further development will be concerned only with particular problems. Furthermore, the practical development of electrical precipitation has now been carried so far that serious difficulties may be anticipated in special cases only. The design of smaller and smaller units is, however, a field in which further development would be profitable. The production of these at an economic price, would be of importance to (national) hygiene, and the curve of development<sup>14</sup> given at the Second World Power Conference in 1930 would then show a sudden increase.

## GENERAL DISCUSSION.\*

Mr. A. G. Grant (Darlington) said: I would like to congratulate Meek and Lunt on their very interesting analysis of energy conditions inside the corona in a wire and tube discharge system. It would be interesting to know if in their work they have been able to throw any light on or draw any conclusions in regard to the conception of "minimum corona energy distance" evolved by Peek in the States, and to some extent accepted here. Peek's view is that in order that corona may occur, it is necessary that the gradient should exceed that necessary for breakdown for a certain minimum distance from the wire, this distance being vaguely connected with the minimum travel necessary for an ion to acquire ionising energy. It seems now that the very detailed analysis made by the authors ought to throw some light on this problem.

Dr. B. W. Bradford (Billingham) said: It is possible in practice to predict the performance of an electrostatic precipitator by the expression due to Deutsch.<sup>1</sup> For the case of the wire in cylinder arrangement, this takes the form:

$$\frac{n_0 - n}{n_0} = 1 - e^{-\frac{2kvt}{R^2 \cdot \ln R/r}}$$

Where  $n_0$  and  $n$  are respectively the initial and final fume ion concentrations,  $k$  is the mean mobility of the fume ions,  $v$  is the applied voltage difference,  $t$  is the time of contact in the precipitator,  $R$  and  $r$  are respectively the radii of the outer and inner electrodes.

This formula is based on the simple assumptions:

- (a) that the combined effects of turbulence and ionic currents preserve a uniform ionic concentration across the cross-section of the tube,
- (b) that the field intensity can be expressed by the classical formula:—

$$X = \frac{1}{x} \cdot \frac{1}{\ln R/r}$$

No assumptions are involved regarding variation of intensity of ionisation in the corona with field intensity, or the average number of ionic charges acquired by fume ions.

There is no doubt that the Deutsch formula is capable of giving an accurate expression of the efficiencies of electrostatic precipitators. For example, by standardising conditions it can be used to determine the mobility of the fume ions in a homogeneous aerosol, and hence the particle

\* On the two preceding papers.

<sup>1</sup> *Ann. Physik*, 1922, **68**, 335; *Z. techn. Physik.*, 1925, **6**, 423.

size, using the expressions derived by Rohman<sup>2</sup> or Ladenburg,<sup>3</sup> for the relation between particle size and the number of charges on the fume ions. The method has been applied to  $H_2SO_4$  mist, and has given excellent results.

It is suggested, therefore, that the factors discussed by the authors, while of fundamental importance in the theory of corona, are not limiting factors in electrostatic precipitators. It follows that no great increase in the efficiency of such precipitators can be expected by working under conditions of maximum energy efficiency of ionisation, whatever these may prove to be for the case of a corona discharge in a turbulent aerosol, which, as pointed out by the authors, are by no means identical with conditions in a particle-free gas.

**Mr. A. G. Grant** (*Darlington*) said: The Deutsch expression throws no light on the voltage-current characteristics of corona, and is to some extent an empirical value presupposing known corona conditions. Work of the type described by the authors is of fundamental importance as leading up to an exact knowledge of corona conditions and data for predicting them. In other words, it aims at elucidating corona discharge itself, rather than dust removal efficiencies in corona applications.

**Dr. R. W. Lunt** (*London*) said: (1) *In reply to Mr. Grant*, the authors have avoided any implications of Peek's "energy distance theory" by using experimental data for the corona diameter;

(2) *In reply to Dr. Bradford*: The authors desire to say that they agree with the views of Mr. Grant; the use of the term "efficiency of a precipitator" is a somewhat arbitrary and partial description of the performance of a precipitator if it is identified only with the fractional precipitation  $(n_0 - n)/n_0$ . The authors' paper refers to the energy efficiency of ionisation, and suggests by implication that this efficiency is one factor determining the energy efficiency of precipitation,  $\eta_D$  particles of dust or mist precipitated per unit of energy supplied. Clearly  $\eta_D$  is proportional to  $(n_0 - n)/(I \cdot V)$  where  $I$  is the current through a precipitator maintained by an electrode potential  $V$ . The Deutsch expression for  $(n_0 - n)$  is not in itself sufficient to predict the variation of  $\eta_D$  with  $V$  and  $r$  under otherwise constant conditions because it supplies no information on the corresponding variation of  $I$  with  $V$  and  $r$ .

It is, at least, a reasonable hypothesis that the rate of production of ions per unit of energy supplied will determine to some extent the rate of charging, and therefore also of precipitation, of aerosol particles per unit of energy supplied. It has been shown that there are reasons for believing that the energy efficiency for ion production may be increased above that for a standard precipitator by increasing  $V$  and diminishing  $r$ ; there is, therefore, reason to anticipate that such a variation of  $V$  and  $r$  will tend to increase  $\eta_D$ , and this is a result that cannot be inferred from a consideration of  $(n_0 - n)/(I \cdot V)$  using the Deutsch expression for  $(n_0 - n)$  alone.

# A COMMERCIAL PLANT FOR REMOVAL OF SMOKE AND OXIDES OF SULPHUR FROM FLUE GASES.

BY G. NONHEBEL.

*Received 2nd April, 1936.*

Simultaneous removal of smoke, dust and acid constituents from flue gases by alkaline water in compact commercial plant has recently been achieved as a result of study of packings for absorptions towers. Such a plant is the Howden-I.C.I. grid packed gas washer, units of which were put into service at Swansea Power Station last year. Further units will shortly be in operation at the new Fulham Power Station. An account of this plant and process together with a survey of the problem of atmospheric pollution in large cities has already been given in *Applied Science Journals*.<sup>1</sup> The physical and chemical problems involved in the design of the plant are, however, of general interest.

## Composition of Boiler Flue Gas.

For the specific case of boiler flue gas, the scrubbing plant may treat gas of composition :—

Grit and dust varying mostly from 5-100 microns . . . . .	1-2 mgs./litre at N.T.P. for stoker firing. 5-15 mgs./litre for powdered fuel firing.
SO <sub>2</sub> . . . . .	0.05-0.20 per cent. (= 1.3-5.2 mgs. SO <sub>2</sub> /litre).
SO <sub>3</sub> . . . . .	Traces <sup>2</sup> up to 10 per cent. of the weight of SO <sub>2</sub> .
HCl . . . . .	Traces of the order of 0.1 mg. HCl/litre.
NO and NO <sub>2</sub> . . . . .	Traces of the order of 0.1 mg./litre of combined nitrogen.
H <sub>2</sub> O . . . . .	Partial pressure of 0.05-0.08 atm.
CO <sub>2</sub> . . . . .	10-16 per cent. by volume.
O <sub>2</sub> . . . . .	9.3 per cent. by volume.

The temperature of the gas will lie between 110° C. and 150° C.

## Description of Plant.

For a process for the removal of the stronger acids such as SO<sub>2</sub> from boiler flue gases to be generally applicable it is necessary to add alkali to the scrubbing water. The consumption of water by the process can then be minimised by recirculation of the wash liquor around the scrubbing towers. Lime or finely ground reactive chalk are the cheapest alkalis available and these are added in the form of a thin milk (5-10 per cent. solids).

Fig. 1 shows the principal items of equipment involved. The gas to be treated is brought by the flue 1 into a distribution chamber, which may be over 25 ft. long and of about 1 second's capacity and from which it flows laterally into scrubbing towers placed along the length of one or both its

<sup>1</sup> Pearson, Nonhebel and Ulander, "The Removal of Smoke and Acid Constituents from Flue Gases by a Non-Effluent Water Process," *J. Inst. Fuel*, 1935, 8, 119, and *J. Inst. Elec. Eng.*, 1935, 77, 1.

<sup>2</sup> H. F. Johnstone, "Corrosion of Power Plant Equipment by Flue Gases," *Univ. of Illinois Engineering Expt. Station Bulletin*, No. 228, June, 1931.

sides. These towers may be up to 12 ft. wide and are about 25-30 ft. high. Uniform gas distribution up through the towers is achieved by

primary elements 2, which consist of vertical wooden boards 3 ft. high and 3 ins. apart placed in echelon as shown in the diagram. These elements are fitted with  $3\frac{1}{4}$ -in. wide pear section tops which collect the whole of the water falling from the packing above and distribute it as a film upon both sides of the elements. The speed of the gas up the empty tower is about 5 ft./sec. The primary elements are supported, however, in such a way that the gap between the pear section tops is only about 1 in so that there is an appreciable resistance to the flow of the gas which assists in the attainment of uniform distribution.

Most of the coarse dust, namely, about half of the total dust, and about half of the  $\text{SO}_2$  in boiler flue gas, are removed by the water passing over the primary elements. This section of the plant can withstand dust loadings of even 30 mgs./litre such as may be

*Diagrammatic arrangement of Howden I.C.I. Flue Gas Scrubber system.*

obtained from a cement kiln. The final scrubbing is effected by a height

of only 3 ft. 6 ins. of a special open grid type of packing 3. The grids found most effective for this duty, as determined by high efficiency and low resistance, are composed of thin wooden laths 1 inch deep,  $\frac{3}{32}$  inch thick, held vertically  $\frac{1}{2}$  inch apart by thin brass or wooden "carriers." The grids are piled on top of each other, the laths of one grid being at right angles to those immediately above and below. The grids are usually built for ease of handling in blocks four sections deep and 4-6 ft. square. The "carriers" are 12-15 ins. apart and are staggered so as to avoid division of the pile of grids into a number of small cells.

The gas rises through the grids and passes out through one or both of the long sides of the towers through spray eliminators 4. These consist of boards about 4 ft. high, 4 ins. wide,  $\frac{1}{2}$  inch thick, and  $1\frac{1}{2}$ -2 ins. apart arranged in a double V or zigzag formation. The height of these boards is chosen so that the velocity of the gas out of the tower does not exceed 6 ft./sec. From the spray eliminators the gas is led along flues to the boiler induced draught fan and delivered to the chimney.

Owing to the large volume of water required to wet the packing and to prevent scale formation thereon (see below), economy in washing water is achieved by recirculation of the used liquor around the scrubbing towers. The main liquor flow is shown by the heavy lines in the diagram. From the pumps 7 the liquor is fed to the head tanks 28, through pipes set at such an angle that the swirl produced is sufficient to prevent settlement of the dust, etc., in suspension. In the base of the head tanks are holes  $\frac{1}{2}$  inch diameter, and about 9 ins. apart through which the water flows on to a 9-inch depth of liquor distributing grids 8. The latter consist of wood bars,  $\frac{1}{2}$  inch square in cross-section and spaced  $\frac{1}{2}$  inch apart, which serve to distribute the water from the nozzles as a fine rain on to the packing.

For efficient utilisation of the scrubbing fluid, it is important that it should flow as a film on the surface of the scrubbing packing. This is because the absorptive capacity of a simple spray is relatively low, since the relative turbulence between gas and liquid is low. The turbulence of the gas as it passes through the grid packing is, on the other hand, appreciable, and is sufficient to throw the humidified dust particles on to the liquor film, which then retains them. Moreover, the liquid is thoroughly mixed as it flows from each layer of laths to the layer at right angles below, and this mixing ensures that there shall be no appreciable concentration of dissolved  $\text{SO}_2$  at the surface of the film which will reduce the absorption rate.

The rain of liquid is therefore fed as a film on to the grids by means of a number of laths 9, set at an angle like a horizontal venetian blind. These film feeders ensure that no free liquid falls through the  $\frac{1}{2}$ -inch square lattice of the grids.

The normal liquor recirculation rate which is required in order to give a sufficiently thick film on the grids to prevent ash deposition upon their surface is 7 litres/hour per cm. periphery of each grid or about 7000 litres/hour per square foot of cross-section of the grid. This gives a film thickness of 0.9 mm.

From the grids and primary elements, the liquid passes through a shallow hopper into a large capacity "delay" tank 6, from which it is pumped back to the scrubbing towers by the pumps 7.

Due to the use of a closed liquor system the water in circulation is saturated with respect to calcium sulphite and calcium sulphate, and can, under certain circumstances, become appreciably supersaturated. One of the principal problems involved in the design of the plant is the control of this supersaturation in order to prevent deposition of scale on the scrubbing surfaces which would choke the tower.

Supersaturated solutions of  $\text{CaSO}_3$  and  $\text{CaSO}_4$  are relatively stable even in contact with crystals of their solid phase, and about 3 minutes in each case are required for a reduction in supersaturation from 5 mg.

equivs./litre to 2 mg. equivs./litre above normal saturation in presence of over 3 per cent. by weight of their crystals. Fortunately supersaturated solutions of these salts do not begin to deposit crystals spontaneously on clean wood (free from crystals) until the level of supersaturation is somewhat over 5 mg. equivs./litre. Consequently the plant is designed so that the liquor is proportioned to the gas rate, its sulphur loading and the degree of oxidation occurring in order to keep the amount of  $\text{CaSO}_3$  and  $\text{CaSO}_4$  formed in each liquor recirculation below 3 mg. equivs./litre. The extent of oxidation which occurs when  $\text{SO}_2$  is absorbed by this solution of calcium bicarbonate is only slightly affected by the oxygen content of the flue gas and is mainly dependent on the oxidation catalysts (Mn, etc.) derived from the lime and the ash and possibly by the small traces of oxides of nitrogen absorbed. With a plant on full load the proportion of total absorbed sulphur appearing as  $\text{CaSO}_4$  varies from 30-50 per cent. with stoker fired boilers to 50-80 per cent. with powdered fuel boilers.

When the sulphur content of the flue gas is less than 3 mgs.  $\text{SO}_2$ /litre, the controlling factor in the size of the scrubbing towers is the maximum gas flow that can be passed through the grids without stripping off the liquor film.

From the last paragraph but one it follows that it is necessary to allow at least 3 per cent. of calcium sulphite and sulphate crystals to accumulate in the liquor and to allow time for crystallisation before pumping the liquor back to the scrubber if building up of supersaturation and consequent scale formation are to be avoided. In plants where the scrubbing towers are in an elevated position, the delay tank can conveniently take the form of a U tube supported on the ground as shown in the diagram. The diameter of the rising leg of the tube is chosen so as to prevent settlement of the suspended solids.

Accumulation of suspended solids above a predetermined level is prevented by purging a small flow of the liquor to a settler 13 or a rotary filter 21, where the solids are removed as a mud containing 30-50 per cent. of water. The clear liquor plus water required to make up losses in the mud and by evaporation is returned through the tank 16, and the pipe 17, to the head tank, where it reduces the supersaturation of the entering circulating liquor.

The quantity of purge is set by reference to an instrument 12, which indicates the specific gravity of the slurry. In one form of indicator this takes the form of a compressed air depth gauge used with a constant depth of flowing slurry.

### Alkali Control.

The milk of lime or chalk for neutralisation of the absorbed  $\text{SO}_2$  is added continuously at 24, just before the delay tank. The increase in  $p_H$  at this point reduces the solubility of  $\text{CaSO}_3$  appreciably and assists rapid crystallisation of this compound.

For efficient  $\text{SO}_2$  removal, and also in order to prevent corrosion of the steel towers and pipes it is necessary to control the  $p_H$  of the circulating liquor fairly closely at  $6.3 \pm 0.2$  at the base of the scrubber. Addition of excess alkali is wasteful, as it is lost as  $\text{CaCO}_3$  in the purge liquor. With control at  $p_H$  6.3, the  $p_H$  after the delay tank seldom rises above 6.8, and since the liquor is saturated with  $\text{CO}_2$ , both lime and chalk are almost completely dissolved as  $\text{Ca}(\text{HCO}_3)_2$ , and this is the effective scrubbing agent. The alkali loss is not more than 10 per cent.

The  $p_H$  is measured by passing a small flow of hopper liquor to a cell 11, containing a glass electrode-calomel combination. The E.M.F. is measured on a Cambridge thermionic valve potentiometer worked off the power mains and the reading is recorded on a chart. Suitable relays can be fitted to the instrument to enable it to control the lime addition valve automatically.

It is found that the solutions render the glass electrodes sluggish and inactive after 5-10 days' service, but they can be readily cleaned with 5 per cent.  $\text{HNO}_3$ .

**Moisture Content of Scrubbed Gases.**—Since the grid scrubber is a highly efficient mass transfer apparatus the gas leaving the plant is saturated with water vapour and is cooled to the wet bulb temperature of the inlet gas. The circulating liquor is at the same temperature.

As the issuing gas is substantially free from  $\text{SO}_2$  and  $\text{SO}_3$ , which might stabilise a mist cloud, the plume of steamy vapour which issues from the chimney rapidly dissipates and becomes invisible.

**Draught Loss.**—Owing to the open nature of the scrubber grids, the draught loss across the whole plant including flues is less than 1 inch water gauge.

**Smoke from Cement Kilns.**—The pilot plant has also been fully tested on gases from a cement kiln. In these experiments the amount of alkaline dust collected by the liquor from the gases was sufficient to neutralise all the  $\text{SO}_2$ . The calcium sulphite served also to absorb most of the  $\text{H}_2\text{S}$  in the gas.

**Pilot Plant.**—Fig. 2 is an isometric view of the complete Pilot Plant at the Billingham works of Imperial Chemical Industries Limited, where the design details of the process were worked out. The various items of the plant can be clearly seen. The scrubbing tower was 4 ft. square.

**Plant Efficiencies.**—The table shows some of the efficiency figures that have been obtained with the Pilot Plant on full load, and also at the powdered fuel power station at Swansea.

Plant.	Substance Measured.	Concentration. Mgs. litre at N.T.P.		Per Cent. Elimination.
		Inlet.	Exit.	
Pilot	Dust from cement kiln	10.4	0.12	98.8
		31.9	0.35	98.9
	Dust from powdered fuel boiler	9.6	0.26	97.2
		11.8	0.21	98.2
Swansea	" " "	—	0.41	{ over 98
			0.32	
Pilot	$\text{SO}_2$ and $\text{SO}_3$ measured as total sulphur	1.87	0.0033	99.8
		1.76	0.0632	96.4
Swansea	$\text{SO}_2$ and $\text{SO}_3$ measured as total sulphur	0.642	0.0018	99.7
		0.834	0.0020	99.7
Pilot	HCl	0.190	0.0061	96.4
"	Oxides of nitrogen as nitrogen	0.171	0.060	65
		0.246	0.091	63

The high efficiency of the plant for dust removal has also been amply shown by the ease with which it removed black smoke from a pulverised coal boiler when combustion conditions are deliberately made bad. The figures show, too, that the high efficiencies predicted from the Pilot plant experiments have been fully confirmed on full size commercial units.

The author's thanks are due to Dr. Lessing for results of laboratory experiments on rates of desupersaturation of calcium sulphate solutions; to the Swansea Corporation and their Consulting Engineers, Messrs. Preece, Cardew and Rider, for permission to publish preliminary figures for Swansea Power Station; and to the directors of I.C.I. (Fertilizer and Synthetic Products) Ltd., and of J. Howden & Co. for permission to publish this paper.

## GENERAL DISCUSSION.

**Mr. W. A. Damon** (*London*) said : As far as I am aware, there are only two plants where efficient removal of acidity from flue gases is practised. One is at Battersea Power Station, where the plant is remarkably efficient. Great credit is due to the London Power Co. for their efforts in this direction, but the Battersea scheme is not of very wide applicability in that it requires for its operation large volumes of naturally alkaline water, such as are available from the Thames. The Howden-I.C.I. plant described by Nonhebel is free from this disability, the only water required being that to make up loss by evaporation. In the event of ample alkaline water being available, can the scrubber operate without recirculation or is it necessary that the scrubbing liquor should have such an alkalinity that recirculation is necessary in the interests of economy?

One would like to see a much wider application of flue gas washing. Dr. Pearson demonstrated in a paper before the Institute of Fuel<sup>1</sup> that the loss to the country occasioned by sulphur oxides in the atmosphere amounted to 10/- per ton of coal burned, and that it was, therefore, an economy to spend anything less than that sum on flue gas washing. The manufacturer, however, does not regard the matter quite in that light. Can Mr. Nonhebel tell us whether he can see any possibility of economy in the operation of the plant by making any use of the calcium sulphate mud which is produced.

**Dr. R. Lessing** (*London*) said that the successful elaboration of a plant and process for the complete purification of flue gases was one of the outstanding achievements in chemical engineering during the last few years. The work leading up to the design of plant and devising the process presented many problems in physical chemistry. Not the least was the prevention of incrustation from supersaturated solutions. He had pointed out six years ago the inexpediency of discharging the spent liquors into water courses and strongly advocated a cyclic, non-effluent system. He was also of opinion that the  $\text{CaSO}_3$  primarily formed should be completely oxidised to  $\text{CaSO}_4$ . This could be done without difficulty and would eventually lead to the commercial utilisation of the product of reaction in form of  $\text{CaSO}_4 \cdot 2\text{H}_2\text{O}$ .

**Mr. G. Nonhebel** (*Billingham*), in reply, said : It would be perfectly possible to use a straight through water system with the process provided sufficient water was available to irrigate the packing, and that water contained sufficient bicarbonate to neutralise the absorbed  $\text{SO}_2$ . Addition of lime to the inlet water in absence of the dissolved  $\text{CO}_2$  present in the recirculating system gives a scale of  $\text{CaCO}_3$  on the pipes and packing. Finely ground chalk is probably not sufficiently reactive. The separation of the dust from the used water of such a straight through system would undoubtedly cause difficulties, owing to the large volume of water involved.

One use to which the solids collected by the system could be put would be the manufacture of plaster. It would be necessary to incorporate in the liquor recirculating system an oxidiser of the type mentioned by Dr. Lessing in order to convert all the calcium sulphite to sulphate. With stoker firing the product would then contain 85-90 per cent.  $\text{CaSO}_4 \cdot 2\text{H}_2\text{O}$ . Until large-scale plants are running, however, it is not possible to predict how the particle size will vary with the inevitable and frequent variations in load experienced in power stations, and reasonable uniformity is essential for such a product.

With very large plants there might be an economic case for utilisation of the mixture of ash and  $\text{CaSO}_3$ , etc., for the production of cement and sulphuric acid.

# IONIC RADII AND HEAT OF HYDRATION.

BY ANDR. VOET.

Received 17th February, 1936.

1. If the reciprocal values of the heats of hydration of the ions of the alkaline metals<sup>1</sup> are plotted against the radii, as given by Pauling,<sup>2</sup>

FIG. 1.

a straight line is obtained. An analogous relation occurs for the ions of the alkaline earth metals<sup>3</sup> as well as for trivalent ions (Fig. 1).

<sup>1</sup> Van Arkel and de Boer, *Chemische Binding*, Amsterdam, 1930.

<sup>2</sup> L. Pauling, *J. Am. Chem. Soc.*, 1926, 49, 765.

<sup>3</sup> Data from *Handbuch der Physik*, 1934, 24<sup>II</sup>—

<sup>4</sup> M. Born, *Z. Physik*, 1920, 1, 45; N. Bjerrum, *Z. physik. Chem.*, 1927, 127, 369.

A similar result was obtained by Webb,<sup>5</sup> who calculated a difference of about 0.53 Å. by the use of electrostriction data.

Since the ion in solution may be defined as a cavity into which the medium cannot penetrate, whilst in crystals the radii are calculated from the distances of the ions, a difference between the two values does not seem unnatural. In the case of an ion in water, the electric dipole, situated in the water molecule, will never approach closer than a fixed distance to the ion, defined as above. Therefore it does not seem improbable that the length of 0.65 Å., which is independent of the nature of the ion, is closely related to the shortest distance between the ion and one of the poles (in this case evidently the negative one) of the water dipole. In this trend of thought a general extension of the Born-Bjerrum equation (2) of the following form may be introduced :

$$H = \frac{Ne^2z^2}{2(r+b)} \left[ 1 - \frac{1}{D} + T \frac{\partial}{\partial T} \left( \frac{1}{D} \right)_P \right], \quad (3)$$

where  $b$  is a constant for each medium, dependent on its molecular structure.

4. Many objections have been brought against the validity of the Born-Bjerrum equation. Calculations carried out on the basis of Debye's theory of dielectrics<sup>6</sup> showed that the dielectric constant of the medium decreases in the vicinity of an ion by electrical saturating effects.<sup>6,7</sup> Recent publications,<sup>8</sup> however, prove that this theory in its original form is inadequate in the case of liquid water where, for instance, the theoretical saturating effect is 3500 times the observed at a field strength of 100,000 volts/cm. It is possible, therefore, that in the Born-Bjerrum equation no electrical saturating effect has to be taken into account.

The energy of electrostriction, which has been calculated by Webb,<sup>5</sup> may be neglected.

One effect which has to be taken into account is the influence on the ion of the electric field of the molecules of the medium. As the negative ions have a high polarisability, the hitherto unknown energy of interaction between anions and water dipoles should be added to the energy calculated from the Born-Bjerrum equation. This interaction might also have an effect on the radius of the anions.

This explains why the empirical relationship between the ionic radii and the heats of hydration of anions does not accord with the modified Born-Bjerrum equation (3). The energy of interaction of cations and water molecules may be neglected, owing to the small polarisability of the positive ions. This difference is emphasized by the eccentric position of the dipole in the water molecule.

Recent publications<sup>9</sup> indicate that the Born-Bjerrum equation is totally inadequate in the case of non-aqueous solutions. Since a proper separation of the hydration energy data of salts into ionic data is impracticable, a direct test of equation (3) seems impossible; as however, it contains a molecular constant, which is different for each medium; it does not seem incompatible with the experiments.

### Summary.

1. A linear relationship has been established between ionic radii and reciprocal heats of hydration of positive ions.
2. An explanation has been proposed on the basis of the electrostatic theory.
3. A modification of the Born-Bjerrum equation is introduced and its validity discussed.

## X-RAY STUDIES OF THE COAGULATION PROCESS OF COLLOIDAL GOLD.—PART I.

BY J. B. HALEY, K. SÖLLNER AND H. TERREY.

*Received 6th April, 1936.*

### Introduction.

The process of coagulation in lyophobic sols has often been investigated with regard to the relation between the rate of coagulation, "zeta" potential and the electrolyte concentration respectively. The experiments have shown that there exists a range of charges where each collision between two particles in solution is unelastic, *i.e.*, if these particles touch they adhere to one another permanently.<sup>1</sup> This range is the so-called region of rapid coagulation.<sup>2</sup> With less discharged particles not every collision is unelastic and only a fraction cause a permanent adhesion; this is the region of slow coagulation.<sup>2, 3</sup> According to von Smoluchowski,<sup>2</sup> in the rapid region, the rate of coagulation is independent of the concentration of the coagulating electrolyte; this has also been proved by experiment.<sup>1</sup> In the slow region, the rate of coagulation is mainly dependent on the "zeta" potential of the particles.

The primary particles in a gold sol are themselves single crystals,<sup>4</sup> while the secondary particles are assumed to be an irregular agglomerate of unchanged primary particles.

The above-mentioned kinetic investigations did not furnish information as to the nature of the secondary particles, which were generally assumed to adhere irregularly and to be unchanged in size or shape.<sup>5</sup> This question was not investigated until recent years owing to the lack of available optical and X-ray experimental methods, the only means by which information can be obtained. With optical methods it has been shown that, during the course of a very slow coagulation, the primary particles may adhere somewhat regularly.<sup>6</sup> Similarly, in some instances where coagulation occurs at the air-liquid interface, such a regular coagulation may become very pronounced with high-speed stirring.

<sup>5</sup> Zsigmondy, *ibid.*, p. 119, *cf.* p. 409.

<sup>6</sup> H. Kautsky in a paper by Zocher, *Z. physik. Chem.*, 1921, 98, 319.

For example, the sols of copper oxide and Goethite do not initially show stream double refraction; this, however, appears after coagulation by stirring, but never after rapid coagulation by electrolytes.<sup>7</sup> Thus, one must assume that the primary particles adhere more regularly during the very slow coagulation brought about by stirring, forming larger, non-spherical aggregates. With optical means it cannot be established, whether this particle growth is due to crystallisation or only to a stable oriented arrangement of unchanged primary particles.\*

In 1921, Scherrer,<sup>4</sup> using the Powder method of X-ray analysis showed that colloidal gold and silver possess the same structure as the macroscopic crystals. This was confirmed by Björnstaahl.<sup>10</sup> Scherrer also showed that it is possible to determine the size of small particles from measurement of the breadths of the diffraction lines. The principle of this method was used by Stoll<sup>11</sup> who concluded, without giving any experimental details, that the particle size of colloidal gold increased upon coagulation. In 1931, Scherrer and Staub<sup>12</sup> showed that the coagulation of highly-dispersed gold sols carried out in the rapid region, produces first an irregular agglomeration of the primary particles, the individual crystals forming these particles having the same size as those of the original sol. Crystallisation of the primary particles could be brought about either by extensive drying of the coagulate or by allowing it to stand in the electrolyte solution. This process proceeded more rapidly at higher temperatures, was greatly hindered by the addition of a protecting agent and did not take place to the same extent with dialysed sols (probably due to some protective action on the particles).

The size of the ultimate crystallite can only be obtained by an X-ray method; other methods give only the magnitude of the secondary particle aggregate and do not permit conclusions to be drawn regarding its intimate structure.

Since Professor Scherrer† does not propose to extend the work reported by Scherrer and Staub,<sup>12</sup> it was decided to carry out a more systematic X-ray study of the coagulation process. One of the main questions to investigate was how far the crystallisation is connected with those functions which are usually linked up with coagulation, namely the

\* The latter possibility must be considered, since many crystalline colloidal particles show a tendency to orient regularly and to form approximately regular aggregates; e.g., in concentrated colloidal solutions of many oxides and dyestuffs containing non-spherical (rod or plate-shaped) particles, the formation of regular aggregates of "tactoids" may easily be seen. If, for example, a drop of an old, concentrated  $V_2O_5$  sol is observed microscopically between crossed Nicols and evaporation is avoided, the "tactoids" appear as bright double-reflecting spots in the course of time. These tactoids are not considered to be crystals since they may be readily dispersed by moving the cover glass on the microscope slide, but form again after a short interval. The ultramicroscope shows that the individual particles forming the "tactoids" have a slow rotary Brownian movement.<sup>8</sup> The directing forces responsible for the formation of the "tactoids" seem to be specific, since in a sol containing particles of two widely different substances (e.g.,  $V_2O_5$  and benzopurpurin) "tactoids" of both substances are formed side by side.<sup>9</sup>

† Private communication to Professor Freundlich.

charge of the particles and the rate of coagulation. In addition, it was decided to investigate the effect, on the rate of crystallisation, of the concentration of the coagulating electrolyte and the period the coagulate was allowed to remain in the electrolyte solution.

The mechanism of this particle growth, as determined by X-ray methods, is not yet definitely established, but many arguments may be advanced for the view that it differs from that usually assumed for relatively insoluble substances such as barium sulphate and calcium carbonate. Here, owing to their higher solubility, the smaller crystals are dissolved and the so-formed ions or molecules separate out of solution on the larger crystals already present. For this reason stable hydrosols of these substances cannot be obtained.

Since gold hydrosols are stable without increase in particle size for practically unlimited periods, but grow rapidly upon coagulation, a similar mechanism of the particle growth seems improbable. It appears more likely that in this and similar cases of substances with an extremely low solubility, the primary particles grow together (i.e., show mass crystallisation) without undergoing intermediate solution, when brought close enough to each other.\*

There has never been any doubt that coagulated particles are close to each other. It is a well-known fact that the dull powders of precipitated gold and silver readily turn macrocrystalline and metallic-looking when gently touched; with higher pressures they form solid metallic masses. These processes are much more rapid at higher temperatures; e.g., Scherrer and Staub<sup>12</sup> found an increase from 69 Å. to 390 Å. on heating a dried gold coagulate for a short time at 300° C.; here the interaction of traces of a liquid solvent seems improbable. Further arguments may be advanced in favour of this view, e.g., the extremely high diffusion coefficient of metallic atoms within metals<sup>15 16</sup> and the rapidity of the particle size increase after coagulation and its hindrance by protecting agents such as gelatin.

For the above reasons it seems probable that the coagulated gold particles unite as such, as soon as they touch each other bodily.† It is then possible for the high atomic mobility within the crystal lattices (which may reasonably be assumed to be much higher at the surfaces ‡) to come into action. Considerations of the structure of "tactoids" seem to establish that the crystals can be brought into suitable positions by the Brownian movement and by molecular forces. The action of such directing forces was realised by Lehmann<sup>17</sup> when investigating, microscopically, the coalescence of crystals of *p*-azoxy ethylbenzoate;

\* Obviously this view was not unfamiliar to Zsigmondy<sup>13</sup> and was the basis of the investigations of Scherrer<sup>4 12</sup> on the crystallisation of colloidal gold. Moreover, it seems reasonable to assume that the different tendency of different substances to show (mass) crystallisation is related to the ultimate difference between reversible and irreversible colloids—a difference which was greatly emphasised by Zsigmondy.<sup>14</sup>

<sup>12</sup> Zsigmondy, *Kolloidchemie*, 4th edn., 1920, p. 19.

<sup>14</sup> *Ibid.*, p. 29.

† This is also necessary for the assumption that the particle growth is due to some localised electrolytic action. (In our opinion, very unlikely.)

‡ This phenomenon, afterwards found to be very common, was first investigated carefully by Volmer and Estermann.<sup>18</sup>

he observed that as two crystals touched one another they were oriented parallel and finally coalesced to form a single crystal.\*

A gold sol was chosen for the following investigations because, in addition to the X-ray and colloidal points of view previously mentioned, effects due to solubility can hardly be considered, so that one may hope to get some insight into the processes which occur during and after the aggregation of the primary particles in the process of coagulation.

The particle size values reported in this paper are only intended to be relative, since it is pointed out in Part 2, which deals with the X-ray technique, that the absolute values may be in error by a factor of 2.

## Experimental.

### Preparation of the Gold Sol.

16 litres of the sol were prepared by the phosphor-gold method as modified by Scherrer and Staub.<sup>12</sup> Conductivity water, obtained from a CO<sub>2</sub>-free Pyrex still was used for the preparation of all the solutions. All vessels were made of Jena glass and were thoroughly cleaned by steaming out for several days. The sol container was of 20 litres capacity. The prepared sol, which is about four times more concentrated than the usual phosphor-gold sol, was slightly acid showing a  $p_H = 6.3$ .

Prior to any experiments, the sol was allowed to stand for 12 weeks. Its particle size was found to be constant throughout the work within the experimental error of the determinations (about 10 per cent.).

The undialysed sol was used for the coagulation experiments in order to obviate any possibility of protection of the particles occurring by the passage of protecting substances out of the dialysing membrane. Such an effect was observed by Zsigmondy<sup>13</sup> and has been discussed by Scherrer and Staub.<sup>12</sup>

### Particle Size of the Original Sol.

A portion of the sol was protected with pure bacteriological gelatin, dialysed in a cellophane sac against frequent changes of conductivity water for 48 hours and finally evaporated down *in vacuo* at 25° C. There was then no trace of potassium, chloride or phosphate ions. The evaporated sample was readily soluble in water, giving the original deep-red colour of the sol. Preliminary experiments on the undialysed sol gave extraneous diffraction lines due to the above-mentioned impurities formed during the preparation of the sol. The diffraction diagram of the original sol is shown in Fig. 1. The particle size being 35 Å.

### Coagulation Experiments.

All coagulations were carried out by the addition, from a microburette, of varying volumes of solutions of aluminium chloride. This electrolyte was chosen because small concentrations readily reverse the charge on the particles and thus the whole region of coagulation can be investigated with one electrolyte. All the reported values of electrolyte concentrations refer to the total volume of the solution after the addition of the electrolyte and are expressed in millimols of aluminium chloride per litre.

The rate of coagulation was judged from the time of the colour change from red to blue after the addition of electrolyte. No exact measurements

\* Here, the cementation of the two crystals may be partially brought about by the dissolved substance present.<sup>17</sup>

<sup>13</sup> Zsigmondy-Thiessen, *Das Kolloides Gold*, p. 48.

of this time were carried out as it was not found possible to judge the exact shade of colour, which varied considerably from sample to sample, with any degree of accuracy. Rapid coagulation, as understood here, is an instantaneous colour change with or without settling of the particles, whilst slow coagulation is a slow colour change over several minutes or hours. In this latter region settling of the coagulate never occurred.

Three standard concentrations of aluminium chloride were used, namely  $M/2$ ,  $M/40$  and  $M/80$ , the choice of concentration depending on the region of coagulation to be investigated. Similarly, two standard volumes of the sol (30 c.c. and 100 c.c.) were used; the smaller volume when evaporation of the protected sol was necessary (*i.e.*, when a sufficient quantity of the sample could readily be obtained) while the larger volume was used when the coagulate was separated by centrifuging, in which case much of the coagulate was always lost owing to the great tendency of the particles to adhere to the walls of the vessel.

All coagulates were protected with excess pure bacteriological gelatin after they had stood in the solution for the requisite time. By this means the possibility of artificial growth of the particles was considerably diminished. In some experiments lysalbinic acid was used as the protecting agent, and was found very efficient for coagulates obtained in the region of slow coagulation, but unsuitable in the rapid region. Where possible, the coagulate was centrifuged out and washed with dilute gelatin solution. Non-settling coagulates, after protection, were dialysed against frequent changes of a dilute gelatin solution for 48 hours and the solution then evaporated down *in vacuo* at  $25^{\circ}\text{C}$ . With this procedure, however, growth of the particles may still take place after the addition of the gelatin. Such an effect has been observed by Scherrer and Staub<sup>12</sup> and is discussed later.

The size of the individual crystals in the coagulate, immediately after coagulation in the rapid region, was obtained from a specimen produced by the addition of excess gelatin immediately after the colour change; the solution was well-stirred, allowed to stand for 20 minutes and the coagulate centrifuged out. The X-ray diagram is shown in Fig. 2.

Coagulates which could be separated from the solution were introduced, in suspension, into the collodion tubes used for the X-ray analysis; the particles were then centrifuged to the bottom of the tube and the process repeated until a sufficient quantity of the sample was obtained. No difficulty was experienced in introducing the evaporated non-settling samples into these tubes.

Since surface forces may modify the particle size of the coagulate, the small amounts present at the air-liquid interface or adhering to the walls of the vessel were neglected.

It was found possible to peptise most of the protected coagulates obtained in the region of slow coagulation, but not those coagulates obtained in the rapid region.

### Cataphoresis Measurements.

These were carried out in order to obtain a rough idea of the magnitude of the charge on the coagulated particles. A standard type of Burton cataphorometer was employed. For settling particles, the supernatant liquid was used as the upper liquid in the cataphorometer; for non-settling particles, an aluminium chloride solution of the same concentration as that in the coagulated solution was used as the upper liquid.

The magnitudes of the charges of the particles are reported relatively to that of the original sol, which is negative (---) as follows:—

(---); (--) ; (—) ; 0 ; (+) ; (++) ; (+++).
Max. negative                      zero                      Max. positive

## Experimental Results.

### Region of Slow Coagulation.

At an aluminium chloride concentration of 0.04 millimols/litre no visible colour change appeared even after 48 hours. The lowest concen-

TABLE I.

tration where a colour change appeared after several hours was 0.06 millimols/litre. In both cases, three samples were protected (1) immediately after the addition of the electrolyte, (2) after 6 hours, and (3) after 48 hours. The results are shown in Table I.

Figs. 3, 4, and 5 respectively show the X-ray diagrams corresponding to a concentration of 0.04 millimols/litre. The sharpening of the diffraction lines, on allowing the solution to stand, is readily observed.

The dependence of the rate of crystallisation on the electrolyte concentration, for a constant time of standing (24 hours) is apparent from Table II(a).

### Region of Rapid Coagulation.

As above, the coagulates were allowed to remain in the electrolyte solution for a period of 24 hours; coagulates above a concentration of 0.17 millimols/litre settled out rapidly but below this concentration they were centrifuged out with difficulty and contained relatively large amounts of gelatin. These results also appear in Table II(b).

### The Dependence of the Rate of Crystallisation on the Time the Coagulate is allowed to remain in the Electrolyte Solution.

The results in the region of slow coagulation have already been given in Table I.; those in the region of rapid coagulation are given in Table III.

### The Effect of Drying the Coagulate.

Two unprotected coagulates of sizes 120 Å. and 130 Å. respectively were dried for 12 hours of  $P_2O_5$  at a pressure of approximately 1 mm. Hg. The final particle size values of both coagulates were indistinguishable from the original values. Similar results were observed by Scherrer and Staub<sup>12</sup> who found that two samples of 69 Å. and 138 Å. respectively also gave, within experimental error, the same values, after drying, as those of the original particles. They explained the failure of these large particles to show any further crystallisation by assuming that some protective action had taken place; this may, however, be explained in a different way (see below).

### Discussion.

Crystallisation of the primary particles occurs even though there has been no visible colour change (Table I.),\* but when a colour change takes place the crystallisation proceeds more rapidly. As previously mentioned, these values are higher than the actual values at the time of addition of gelatin to the solution, since crystallisation proceeds during dialysis, even after the particles are protected. The values of 50 Å. and 70 Å. respectively in Table I. are not in agreement with the value of 43 Å. obtained in the rapid region of coagulation (Table III.), where the particles are quickly separated from the electrolyte solution by centrifuging.

From Table II(a.), it is evident that, in the region of slow coagulation, for a constant period of standing in the electrolyte solution, the rate of

\* Bearing in mind that this visible method is very rough, this increase may readily be explained by the fact that low electrolyte concentrations favour the formation of small aggregates, probably with many of the primary particles remaining unchanged. In the normal course of events (*i.e.*, when the rate of coagulation is greater than the rate of crystallisation of the primary particles) the appearance of a blue colour indicates the formation of irregular, loose-packed aggregates. Owing to the size of these aggregates, both the state of loose-packing and the blue colour may still remain even after considerable internal crystallisation has taken place. However, crystallisation of the very small aggregates formed at very low electrolyte concentrations, may cause both the state of loose-packing and the blue colour to disappear. Such a sol, although possessing greatly increased particle size, may still be red, since gold sols with primary particles up to 1200 Å. are often this colour.<sup>10</sup> <sup>21</sup> Since, in the experiments recorded in Table II(a.), the blue colour never appeared, the results seem to indicate that the rate of crystallisation is greater than the rate of coagulation.

<sup>20</sup> Zsigmondy-Thiessen, *Das Kolloide Gold*, p. 120 *et seq.*

<sup>21</sup> Zsigmondy, *Kolloidchemie*, 3rd edn., 1920, p. 160 *et seq.*

crystallisation depends directly upon the electrolyte concentration and thus on the rate of coagulation.

Table II(b). shows that under the same conditions in the region of rapid coagulation, the extent of the crystallisation is equal and independent of the concentration of the coagulating electrolyte—both with negative and positive coagulates.

The combined results indicate that the crystallisation is directly dependent on the rate of coagulation; no abnormal effect was observed near the iso-electric point, such as might be expected where the electrokinetic charge of the particles is zero.

The results of Table III. and to some extent those of Table I. show that the maximum crystallisation takes place within a very short time after the addition of the electrolyte, in the rapid region of coagulation. Although this process continues with increasing time of standing in the electrolyte solution, the relative speed rapidly diminishes. The results also confirm those of Scherrer and Staub,<sup>12</sup> namely rapid coagulation causes at first an irregular agglomeration of the primary colloidal particles (Fig. 2) and, thus, also the basic ideas of the von Smoluchowski theory of rapid coagulation.<sup>2</sup> These irregularly aggregated (or at least incompletely oriented) particles are afterwards oriented (mainly rapidly), forming bigger crystalline units.

These results seem to favour the assumption of a mass crystallisation phenomenon, as set out in the introduction. Thus the close parallelism between rate of coagulation and particle growth can be understood on the same basis, namely the interaction of the attracting (and directing) and repelling forces between the particles.

It may be said, especially against the results in the rapid region, that the size of the crystals, as found by the X-ray method, may be quite different from the actual size of the masses of material bound together by primary linkages. The formation of an extended skeleton could not be detected by X-ray methods. Since the particles are not of uniform size and are not necessarily regular in shape, only a limited number of particles would be able to adhere regularly and without any skeleton formation.\* Furthermore, a defective arrangement or incomplete orientation of the crystals would affect the diffraction line breadths and lead to illusory values for the size of the crystals formed by aggregation. In this way the limiting value of 120 Å.-130 Å. (Table II(b).) and the failure of the particles to show any further crystallisation when dried, could be easily understood. Further investigations, both by X-ray and ultra-microscopic methods, with sols of different primary particle size, prepared either by different methods or with a different substance (*e.g.*, silver) may overcome these difficulties.

The authors wish to express their thanks to Professor F. G. Donnan, C.B.E., F.R.S., for his interest in the work; to Professor H. Freundlich for his valuable advice; and to Mr. G. S. Hartley for the supply of conductivity water.

### Summary.

Coagulation of a highly-dispersed gold sol causes the primary particles to form, at first, an irregular agglomerate, the individual crystal size of which is the same as that of the original sol.

\* Cubes of different sizes or octahedra (the generally assumed shape of colloidal gold particles) of equal sizes cannot be packed together in space without interstices.

Crystallisation of the primary particles may be brought about by allowing the coagulate to remain in the electrolyte solution.

The crystallisation is dependent on the rate of coagulation and is constant over the whole region of rapid coagulation. In this latter region the maximum growth takes place very rapidly.

## X-RAY STUDIES OF THE COAGULATION PROCESS OF COLLOIDAL GOLD. PART II. X-RAY EXPERIMENTAL TECHNIQUE.

BY J. B. HALEY AND H. TERREY.

*Received 6th April, 1936.*

The X-ray method of particle size determination depends on the line broadening observed in the Powder diffraction diagram when the individual crystal size falls below approximately  $10^{-8}$  cm.

A connection between the breadths of the diffraction lines and the size of the particles under investigation was first pointed out by Scherrer<sup>1</sup> who derived the following equation for cubic crystals:—

$$B = 2\sqrt{\frac{\log_e 2}{\pi}} \cdot \frac{\lambda}{A} \cdot \sec \theta + b, \quad (1)$$

where:  $B$  is the line breadth in angular measure;  $A$  the particle size (cube edge);  $\theta$  the glancing angle of X-ray reflection;  $\lambda$  the wavelength of the incident radiation;  $b$  a constant depending on the specimen diameter; and the definition of the incident radiation.

The line breadth is generally defined as the ratio of the integrated X-ray intensity across the diffraction line, to the maximum intensity, i.e.,  $B = 1/I_{\max} \int I \cdot dx$ , where  $I$  is the intensity and  $x$  the lateral distance in the scale of the diagram. This measurement is somewhat difficult to make in practice and it is more usual to measure the line breadth at half the maximum intensity. The former method, however, tends to give values which are more independent of the shape of the intensity curve of the diffraction line than the latter.

From equation (1), it is apparent that the relation between  $B$  and  $\sec \theta$  should be linear and the slope of this graph is equal to  $2\sqrt{\frac{\log_e 2}{\pi}} \cdot \frac{\lambda}{A}$ ; from which the particle size  $A$  can be calculated. The intercept on the  $B$  axis gives the value of  $b$ .

Two of Scherrer's assumptions (namely parallel incident radiation and transparent sample) are difficult to realise in practice. Brill<sup>2</sup> and Cameron<sup>3</sup> have pointed out that with *divergent* radiation and transparent samples, the line breadths at small angles become very large

<sup>1</sup> P. Scherrer, Zsigmondy, *Kolloidchemie*, 3rd edn., 1920, p. 394.

<sup>2</sup> R. Brill, *Z. Krist.*, 1928, **68**, 387.

<sup>3</sup> G. H. Cameron, *Physics*, 1932, **3**, 57.

Fig. 1, *i.e.*, the slope of the  $B/\sec \theta$  graph is very small or even negative. If, however, the sample is strongly absorbing, either in itself or is made so by coating it on a lead glass rod, the two defects oppose one another with a marked reduction in the central line breadths (Fig. 2). Thus, in favourable circumstances, the Scherrer condition (that  $B$  is a linear function of  $\sec \theta$ ) may accidentally be realised.

Equations, similar to that of Scherrer, have been proposed by Seljakow<sup>4</sup> and Randall, Rooksby and Cooper;<sup>5</sup> these, which are based on assumptions similar to those outlined above, differ only in the value of the numerical constant.

Von Laue<sup>6</sup> has given a more general theoretical analysis where the crystals are not confined to those of the cubic system. The radiation was assumed to be purely divergent:

$$B = \frac{\pi \cdot \frac{\omega}{\eta} \cdot \left(\frac{r}{R}\right)^2 \cos^3 \theta}{\sqrt{1 + \left(\frac{\omega r}{\eta R} \cdot \cos^2 \theta\right)^2 - 1}}, \quad (2)$$

where:  $B$  is the absolute corrected value of the line breadth in angular measure;  $\theta$  the angle of reflection;  $\omega$  a constant (0.55);  $R$  the camera radius and  $r$  the specimen radius.

$\eta$  is a quantity related to the particle size by a complex expression which, for cubic crystals, reduces to:—

$$\eta = \frac{\lambda}{4\pi A}, \quad (3)$$

where  $\lambda$  and  $A$  have the same significance as before.

### Brill's Modification of von Laue's Theory.

Brill<sup>2</sup> has shown that, for a completely absorbing solid cylindrical sample and for infinitely large particles, the experimental line breadths  $B'$  will be connected with the  $B$  used by von Laue by the following expression:—

$$B = \frac{B'}{\sin^2 \theta}. \quad (4)$$

Brill's procedure was to correct the measured line breadths by equation (4); reduce to absolute values in angular measure and, for cubic crystals, to calculate the particle size by equations (2) and (3). Finally, since complete absorption may not be obtained in a thin layer at the surface, the calculated particle sizes from each diffraction line were plotted against  $\sin^2 \theta$  and extrapolated to find the size at  $\sin^2 \theta = 1$ , since at  $2\theta = 180^\circ$  absorption is assumed to have no effect.

This procedure has been criticised by Cameron;<sup>3</sup> *e.g.*, the accuracy of the final result depends on the presence of one or more diffraction lines at large angles of reflection, which is often difficult to achieve; in addition, the correction for absorption (equation 4) was developed for parallel radiation, while von Laue's theory was developed for purely divergent radiation; moreover, the correction was developed for sharp lines, *i.e.*, the effect of absorption on the line broadening due to small particles was

<sup>4</sup> Seljakow, *Z. physik. Chem.*, 1925, 31, 439.

<sup>5</sup> Randall, Rooksby and Cooper, *Z. Krist.*, 1930, 79, 196.

<sup>6</sup> M. von Laue, *ibid.*, 1926, 64, 115.

neglected. However, he concluded that, while in many cases, the final results may err by a factor of 2 in absolute value, the methods of Scherrer, von Laue and Brill were capable of arranging a series in the correct order of size with considerable precision.

The Brill and Pelzer Total Absorption method <sup>7</sup> was not used in the experimental work reported below owing to the difficulty of coating thin, even layers of gelatinous samples on the lead glass rod. It is essential that this layer is thin otherwise the line breadths at low angles tend to be excessively large, while an uneven layer produces lines whose intensity, on either side of the centre, is unequal (*cf.* Fig. 7).

### Experimental.

The X-ray diffraction diagrams were obtained in a Powder camera of 28.29 mm. radius, with a pinhole 1 mm. diameter. Cu K $\alpha$  radiation was

FIG. 3.

used throughout; the  $\beta$  component being eliminated by means of a Ni filter. The average exposure time (at 40 Kv and 20 Ma) was 15 minutes, which was found to produce line densities falling within the limits (0.2 and 0.65) required for the correct intensity interpretation of the films. All the specimens were supported in thin collodion tubes ranging in diameter between 0.4 and 0.8 mm.

The difference in photographic contrast between various films was minimised by utilising a standard time of development (4 minutes at 17° C.) with a metol-hydroquinone developer; the film container was rocked to ensure uniform development.

All films were photometered on a Zeiss self-registering microphotometer.

<sup>7</sup> Brill and Pelzer, *Z. Krist.*, 1930, 74, 147.

### Determination of the Intensity-Deflection Relation.

For the correct intensity interpretation of the diffraction lines it is essential to know the relation between the intensity of the X-ray beam producing a given deposit on the film and the deflection of the photometer fibre when this spot is photometered. The density  $D$  of a given deposit on the film may be defined by the relation  $D = \log_{10} \frac{I_0}{I}$ ; where  $I_0$  is the intensity of a beam of light from a constant source after it has passed through the film exposed to the general radiation on either side of the deposit and  $I$  is the intensity after passing through the deposit itself.

A great deal of work has shown that, for densities up to about 0.8, there is a linear relation between the X-ray intensity producing a given deposit on the film and the density of that deposit.<sup>9, 9, 10, 11, 12, 13</sup>

The relation between the microphotometer deflection and density was determined by placing 1, 2, 3 . . . strips of equally exposed and developed film in the path of the light falling on the photocell and measuring the corresponding deflection. The density of each strip, from an independent calibration, was  $0.132 \pm 0.007$ . The ordinates of the experimental graph (Fig. 3) represent the differences in deflection  $(y_0 - y_1)$ ;  $(y_0 - y_2)$  . . . where  $y_0, y_1, y_2$  are the deflections corresponding to 0, 1, 2 . . . strips of film. In reality this curve is exponential, however, between densities of approximately 0.2 and 0.65 (deflections between 20 and 60 mm. or differences of 40 mm.) it is nearly linear; this assumption, though not strictly accurate, greatly simplifies the line breadth determinations, the error involved being only a few per cent. as is seen from Table I. of three typical uncorrected line breadths (in linear measure) determined by various methods:

I. By measurement of the "half intensity width" assuming the above linearity (for further details see below).

II. As I., but measuring on the more correct log (deflection) curve.

III. As I., but measuring on the photometer curve replotted in terms of density by interpolation from the density-deflection curve.

IV. By measurement of the line breadth from the definition

TABLE I.

Planes	I	II.	III.	IV.
133	1.20	1.17	1.18	1.23
024	1.11	1.13	1.14	1.24

$$B = \frac{1}{I_{\max.}} \int I \cdot dx$$

using Miles's method.<sup>14</sup>

Relative variations do not affect the results of Part I., which are only intended to convey relative orders of magnitude.

### Measurement of the "Half-Intensity Width."

In order to obtain a reasonably high linear magnification of the curves, the diffraction diagrams were photometered in two separate parts; namely the planes 111 to 222 inclusive and 133, 024 and 224 with magnifications of 6.55 and 9.46 respectively. The omission of the 004 plane is of no

<sup>13</sup> F. D. Miles, *Trans. Faraday Soc.*, 1935, **31**, 1452.

<sup>14</sup> F. D. Miles, *Phil. Trans. A*, 1935, **235**, 124.

consequence as it was, in almost every case, too weak for any accurately measurable deflection to be obtained from it. Two typical photometer records from a diffraction diagram corresponding to a particle size of 130 Å. (Fig. 7 in Part I) are shown in Figs. 5 and 6.

The "Half-Intensity Width" of the diffraction lines is represented by the line breadth at half the difference between the background and peak deflections; both the latter being measured from zero deflection (*i.e.*, with no light falling on the photocell). Where necessary, these values were corrected for slope of the background by Brill's formula,<sup>3</sup> yielding final values of  $b$ . The actual line breadth ( $b'$ ) in linear measure is then  $b/M$ , where  $M$  is the photometer magnification.

For the experimental use of the Scherrer equation the values of  $b$  were converted into absolute angular measure  $B'_{\text{abs}}$ , by division by the camera radius. For the Brill method the values of  $b'$  were corrected:

(a) where necessary, for asymmetry of the photometer curves, by Brill's formula.<sup>3</sup>

(b) For absorption by equation 4. These values were finally converted into angular measure  $B_{\text{abs}}$ , as above.

### Application of the Scherrer Equation.

The particle size  $A$  was calculated, using the method of least squares, from the following equation:—

$$A = \frac{2\lambda \sqrt{\frac{\log_e 2}{\pi}} \left[ n \sum \sec^2 \theta_n - \sum \sec \theta_n \right]}{n \sum B'_{\text{abs}} \sec \theta_n - \sum B'_{\text{abs}} \sum \sec \theta_n}$$

In view of the strongly absorbing properties of gold and of the divergent X-ray beam employed, the linear relation between  $B$  and  $\sec \theta$  might be

FIG. 8.

expected to hold. This was found to be the case with samples which could be readily centrifuged out of solution, however, with samples containing a large amount of gelatin, *i.e.*, those which centrifuged out with difficulty and those which required evaporation, this linear relation no longer held. The difference between the

two cases is no doubt due to the lowering of the specimen absorption on diluting the specimen; this is supported by the observation that it was often difficult to see the shadow cast by the specimen on the fluorescent screen in the camera with the latter class of specimens, while no such difficulty was observed with the former class. In addition, the exposure time for the latter class would decrease *always* 40 per cent. or so in order to produce satisfactory line densities. The central line broadening which is consistent with such a suggestion, may be seen in many of the reproductions in Part I, and also in Fig. 6 of this part. It will be observed that this is in every way identical with the diffraction diagram of the very transparent MgO (Fig. 1). The

effect of making it strongly absorbing is shown in Fig. 7, it is seen that although there is a slight reduction in the central line breadths, the effect is not as great as might be expected from a comparison of Figs. 1 and 2. This, however, is most probably due to the layer not being sufficiently thin.

The effect of this decrease in absorption on the  $B/\sec. \theta$  graph is shown in Fig. 8: OR is a curve obtained from a sample containing excess gelatin, it is seen that the central line breadths are very large as in Fig. 6; QR represents the linear relation as would be expected from the form of the Scherrer equation and is that actually obtained from samples containing a small amount of gelatin; PS is the slope of the experimental curve OR as obtained by the direct application of least squares to the experimental line breadths, thus in this latter case the calculated particle sizes become either very large or even negative. Cameron<sup>2</sup> has reported a similar effect when using samples of low atomic weight, *i.e.*, of low absorbing properties. It was not considered justifiable, in view of the unsatisfactory state of affairs existing with regard to this equation, to calculate the particle sizes using the line breadths from the three major angles as is done, in similar circumstances, with the Brill method below.

### Application of the Brill Method.

The unsatisfactory results obtained by the use of the Scherrer equation led to the employment of Brill's first modification of von Laue's theory. An account of this method has already been given.

FIG. 9.

Two typical extrapolation graphs to find the particle size at  $\sin^2 \theta = 1$  are shown in Fig. 9. The corresponding particle sizes being 98 Å. and 128 Å. respectively. The upper graph AC (98 Å.) is that obtained from a sample containing a large amount of gelatin; the effect of the central line broadening is again apparent as in Fig. 8, *i.e.*, the calculated particle sizes from these low angles are much lower than would be expected from the more reliable large angles. In the lower graph AD (128 Å.), the extrapolation, as would be expected, passes through all the points. In all cases the extrapolation was carried through the points obtained from the large angles ( $55^\circ$  to  $67^\circ$ ); the existence of these lines at large angles removes one of the main objections to the method.<sup>3</sup>

All the particle sizes for the experiments recorded in Part I. were obtained in this way. It was, on the whole, found entirely satisfactory in arranging the results in the correct order of magnitude without reference to the absolute values of the sizes.

### Summary.

This paper deals with the experimental technique involved in the determination of the particle sizes of the various coagulates reported in Part I.

The Scherrer equation was found unsatisfactory for samples which had been diluted with gelatin, *i.e.*, when the sample was no longer strongly absorbing. This confirms the general conclusions of von Laue, Brill and Cameron.

The reported results were calculated from Brill's first modification of von Laue's theory, which was found satisfactory for placing the results in the correct order of size without reference to their absolute values.

The authors wish to express their thanks to Professor F. G. Donnan, C.B.E., F.R.S., for his interest in the work.

## DIPOLE MOMENT AND MOLECULAR STRUCTURE. PART XVII.\* THE DIPOLE MOMENTS OF AZO-DYES AND SOME SIMILAR SUBSTANCES.

BY ERNST BERGMANN AND (MISS) ANNA WEIZMANN.

*Received 14th April, 1936.*

The constitution of the amino- and *p*-hydroxy-azo-dyes seems quite settled, but that of the *o*-hydroxy-azo-compounds is still a matter of discussion. A new point of view has been introduced by R. Kuhn,<sup>1</sup> who proposed a Zwitter-ion structure (I),<sup>2</sup>

combining in itself to a certain extent both of the azoid (II) and quinoid (III) formulæ,

\* Part XVI., *J. Chem. Soc.*, 1936, 402.

<sup>1</sup> *Naturwiss.*, 1932, 20, 619.

<sup>2</sup> Such formulæ had already been suggested by P. Blumberger, *Chem. Weekblad*, 1927, 24, 1.

The occurrence of such a form, even in small quantities, should be readily detectable, since its dipole moment should be abnormally high (about 20 D.). We have therefore determined the dipole moment of several azo-dyes (not only *ortho*-hydroxy-azo-dyes), both in order to compare their dipole moments and to determine the structure of *p*-hydroxy-azo- and amino-azo-compounds, in which the possibility of the same isomerism or tautomerism has never been excluded by decisive experiments (Table I.).

\* The figures have the following significance: *c* molar fraction,  $\rho$  density,  $\epsilon$  dielectric constant,  $n$  refractive index,  $P_{\frac{1}{2}}$  total polarisation ( $PE_{\frac{1}{2}}$  electronic polarisation) for the solution,  $P(PE)$  the same for the solute,  $P_{A+0}$  atomic and orientation polarisation, which is extrapolated graphically to infinite dilution ( $P_{A+0}^\infty$ ).

For part of the substances we had at our disposal an Abbé refractometer; for the others the Zeiss interferometer, which which, however, it is not possible to determine the refractive index of highly coloured substances, at least not at the same concentrations as the dielectric constant. In these cases  $PE$  was calculated from the atomic and bond refractivities, or was determined at much lower concentrations, the average of the observed values being used in the case of high concentrations. This procedure is justified, since  $PE$  does not depend on the concentration.

## 1. Zwitterion Formulæ.

Since the values for the *ortho*-hydroxy-azo-dyes are not abnormally high, we conclude that these substances cannot contain remarkable amounts of the Zwitterion-form in their solutions. Indeed, Kuhn himself has recently<sup>3</sup> shown that 4-benzene-azo-1-naphthol does not raise the dielectric constant of its solvents, pyridine and nitrobenzene. It is very remarkable that the *p*-amino-azo compounds have anomalously high moments, as compared with the "normal" values of aniline 1.55,<sup>4</sup> *N*-dimethylaniline 1.58,<sup>5</sup> and  $\alpha$ - and  $\beta$ -naphthylamine (see Table I.), the higher value for the  $\beta$ -isomer agreeing with earlier data.<sup>6</sup> Obviously, *p*-amino-azo compounds should have the dipole moment of the group  $\text{NR}_2$ , since such compounds as azo-benzene have zero moments.<sup>7</sup> Here, again, two formulæ (IV) and (V) are possible:

<sup>3</sup> *Annalen*, 1935, 516, 143, 151, published some time after our preliminary publication, *Chemistry and Industry*, 1934, 54, 150.<sup>4</sup> Hassel and Uhl, *Z. physik. Chem., B*, 1930, 8, 187.<sup>5</sup> Fogelberg and Williams, *Physik. Z.*, 1931, 32, 27.<sup>6</sup> Parts, *Z. physik. Chem., B*, 1930, 10, 264; Nakata, *Ber.*, 1931, 64, 2059.<sup>7</sup> Bergmann, Engel and Sandor, *Ber.*, 1930, 63, 2572.

The more reasonable seems to be (V), since only that structure provides equally for the formation of amino- and dimethylamino-azo-benzene, without migration of an hydrogen atom,<sup>8</sup> and seems to explain how, by addition of acid on the ends of the charged system, they form salts.

These particular "anomalous" compounds are not unique. The abnormally high dipole moment of *p*-nitraniline<sup>9</sup> must certainly be accounted for by VI, since its N-dimethyl-derivative has a still higher

moment (6.87).<sup>10</sup> It may be pointed out that the differences between the moments of amino- and N-dimethylamino-azo-benzene (0.97) and amino- and N-dimethyl-amino-nitrobenzene (0.72) are of the same order.<sup>10a</sup> According to Hassel and Naeshagen,<sup>11</sup> *p*-amino-acetophenone has too high a moment. Here, too, the compound may exist partly in an excited form such as VII. The ability of the carbonyl group to be converted into a semipolar double bond system (VII) has been discussed by McKenzie and his co-workers.<sup>12</sup> Furthermore, as we have pointed out,<sup>3</sup> the unusually high moment of nitroso-dimethylaniline may easily be explained

by VIII, which accords with its chemical properties (hydrolysis to dimethylamine and *p*-quinone-monoxime, interaction with methyl iodide and with benzoyl chloride). Other explanations might be given; for instance, one might assume mesomeric forms between the classical and our formulæ,<sup>13</sup> or, what seems essentially the same, resonance between the two forms.<sup>14</sup> Obviously, one cannot, by dipole moments alone, decide which is the most suitable.<sup>15</sup> In the case of 1-benzene-azo-2-naphthylamine (the moment of which is not very different from that of 2-naphthylamine), one would accordingly assume that the proportion of Zwitterion molecules is somewhat small, or even zero, since the small difference between the two moments may easily be explained as due to an "ortho-effect" of the double bond on the C—OH— moment.<sup>15a</sup>

<sup>8</sup> For similar observations see Burawoy, *Ber.*, 1931, 64, 462, 479.

<sup>9</sup> *Trans. Faraday Soc.*, 1934, 30, lxxii; and Porter and Kumler, *J. Am. Chem. Soc.*, 1934, 56, 2549.

<sup>13</sup> Le Févre and Smith, *J. Chem. Soc.*, 1932, 2239.

<sup>14</sup> Sutton, *Trans. Faraday Soc.*, 1934, 789.

<sup>15</sup> Compare Arndt, *Ber.*, 1930, 63, 587, 2963, 3125.

<sup>15a</sup> See the following paper.

## 2. Structure of *p*-hydroxy-azo-dyes.

Zwitterion formulæ for the *p*-hydroxy-azo-dyes are ruled out by their relatively low dipole moments. It remains to decide whether the dyes are quinoid or azoid compounds, and whether, indeed, an uniform formulation is possible. The dipole moment of *p*-hydroxy-azo-benzene in benzene solution is the same as that of phenol,<sup>16</sup> so that its structure (IX) seems unambiguous, its moment being exclusively determined by that of the hydroxyl group. Again, *p*-methoxy-azo-benzene has a moment nearly identical with that of anisole.<sup>17</sup> As a matter of fact, *p*-hydroxy- and *p*-methoxy-azo-benzene have in benzene solution identical absorption.<sup>18</sup>

Whilst the dipole moment of 4-benzene-azo-1-methoxy-naphthalene is sufficiently near to that of the methoxy-group in anisole to give a clue to the formulated structure, it is difficult to see why the corresponding hydroxy-compound and *p*-hydroxy-azobenzene have a somewhat high moment in dioxane solution, especially since azo-benzene itself has nearly the same total polarisation (which in this case is identical with the electronic polarisation) in benzene and dioxane. The change must therefore be structural, involving a partial (tautomeric) change into a quinoid hydrazone structure.<sup>19</sup>

## 3. Structure of *ortho*-hydroxy-azo-dyes.

For *o*-hydroxy-azobenzene and 1-benzene-azo-2-naphthol, the dipole values are those of the hydroxyl group; an azoid structure, in the solutions we have used, would be at variance with the spectroscopic findings of Burawoy and Markowitsch,<sup>20</sup> who state that all the *o*-hydroxy-azo compounds are quinone-hydrazones. Kuhn and Baer,<sup>18</sup> however, on spectroscopic grounds, assume the azoid structure for *o*-hydroxy-azobenzene (similarity between the *o*- and *m*-hydroxy-azo-benzene bands), but a quinoid formula for 1-benzene-azo-2-naphthol. Since the influence of a possible chelation<sup>20a</sup> cannot be evaluated, the dipole moments in the two above cases do not lead to any decision. On the other hand, our measurements with 2-benzene-azo-1-naphthol seem to agree with the spectroscopic findings and to show that the substance has (quinoid) hydrazone structure, because the difference between the dipole moments of the azo-dye and of the (certainly quinoid)  $\beta$ -naphthoquinone-benzyl-phenylhydrazone is no greater than that between the moments of benzophenone-phenylhydrazone and -benzylphenylhydrazone.

<sup>16</sup> Donle and Gehrkens,  $1.61 \pm 0.03$ ; *Z. physik. Chem.*, B, 1922, 18, 316.

<sup>17</sup> Donle and Volkert, 1.23; *Z. physik. Chem.*, B, 1930, 8, 60.

<sup>18</sup> Kuhn and Baer, *Annalen*, 1935, 516, 155.

<sup>19</sup> The various hydrazones we have investigated have dipole moments of the same magnitude as those under discussion; the dipole moment to be expected for (XI) cannot, of course, be calculated theoretically from the dipole moments of, say, benzophenone-phenylhydrazone and the carbonyl group, since the hydrazone group has no axial symmetry. Kuhn and Baer<sup>18</sup> recently observed spectroscopically such a structural shift under the influence of solvents, even in the case of 4-benzene-azo-1-naphthol. (The possibility of tautomerism of *p*-hydroxy-azo-compounds has been mentioned by Borsche, Mueller and Bodenstein, *Annalen*, 1929, 472, 20; in a certain number of such substances Lauer and Miller (*J. Am. Chem. Soc.*, 1935, 57, 520) have proved a quinonoid activity.)

<sup>20</sup> *Annalen*, 1933, 503, 197; 1933, 504, 60.

<sup>20a</sup> Compare Blumberger, *Chem. Centralbl.*, 1935, I, 3273.

## 4.

Measurements of dipole moments may, as a rule, be used for detecting substances of the Zwitterion type, since these should exhibit an unusually high electric moment. As a matter of fact, the method has been used qualitatively for amino-acids and peptides,<sup>21</sup> and also for other organic molecules.<sup>22</sup> Two new cases, xanthone and quinoleine yellow are here discussed. The dipole moment of xanthone should be equal to the difference between those of the carbonyl group<sup>23</sup> and of xanthene, the moment of which is due exclusively to the diphenyl ether system, participating in the ring—the assumption being made that the xanthene system is plane. The moment (1.28) for xanthene agrees reasonably with that of diphenyl ether.<sup>24</sup> The "normal" moment of xanthone should be therefore  $2.95 - 1.28 = 1.67$  D, whilst that observed is as high as 3.07. The unusually low chemical activity of xanthone agrees with the conclusion that the moment is due to the fact that part of the xanthone molecules exist in a Zwitterion state (XIII).<sup>25</sup>

For quinoleine yellow, a Zwitterion formula (XV) was once suggested by R. Kuhn,<sup>26</sup> instead of the "unexcited" formula (XIV), and now withdrawn.<sup>27</sup> Our measurements confirm this; the value of 3.64 for the

dipole moment in dioxane solution is not low but, since quinoleine<sup>28</sup> itself has a moment of 2.14, only a small fraction of the molecule can exist in Zwitterion form.

# DIPOLE MOMENT AND MOLECULAR STRUCTURE. PART XVIII. THE DIPOLE MOMENTS OF SUBSTITUTED $\alpha$ -METHYL-STYRENES.

BY ERNST BERGMANN AND (MISS) A. WEIZMANN.

Received 14th April, 1936.

*Ortho*-disubstituted benzenes have anomalous dipole moments, differing from the vectorial sum of the single group-moments. One may explain the "ortho-effect," by assuming either that the group moments remain constant, there being a widening of the angle of the substituent valencies owing to the "volume" of the substituents,<sup>1</sup> or that the group moments change by mutual induction, whilst the direction of the ring-substituent bonds remains constant<sup>2</sup>; or, again, both effects may apply at the same time.

That *widening of the angle* between *ortho*-substituents occurs to a certain extent, has since been demonstrated.<sup>3</sup> In order to ascertain the magnitude of the *induction effects* concerned, we have studied in benzene solution the dipole moments of several *ortho*-substituted  $\alpha$ -methylstyrenes: since the

ethylenic group, having no marked dipole moment, is highly polarisable. In view of the smallness of the carbon atoms, it is unlikely that X is deflected from its normal direction.<sup>4</sup> The theoretical dipole moment of the *ortho*-substituted  $\alpha$ -methylstyrenes should be equal to the sum of the moment of X and the resultant moment of the unsaturated system. The latter should be about 0.5 and parallel to the moment of the nucleus-X bond, since it results from the styrene moment,<sup>5</sup> and the methyl moment, the angle between the C-methyl and the C-phenyl bond being assumed to be  $120^\circ$ .<sup>6</sup> Induction would, as usual, tend to decrease the expected moment of (X + 0.5).

Table I. shows that there is a marked influence, except in the first case, where the theoretical moment has actually been found; *o*-xylene, however, also has the theoretical moment.<sup>7</sup> In  $\alpha$ -naphthyl-methylethylene, already, the expected moment has fallen to zero. Comparing

<sup>1</sup> Suggested originally by Bergmann, Engel and Sandor, *Z. physik. Chem. B*, 1930, 10, 106, as a working hypothesis which proved quite satisfactory (compare Hassel and Naeshagen, *ibid.*, 1931, 12, 79).

TABLE I.

Compound.	Dipole Moment (Benzene Solution).	Group Moment of X.
$\alpha$ -Dimethylstyrene . . . . .	0.8	0.4
$\alpha$ -Naphthyl-methyl-ethylene . . . . .	0	0
<i>o</i> -Methoxy- $\alpha$ -methylstyrene . . . . .	1.48	1.23
<i>o</i> -Fluoro- $\alpha$ -methylstyrene . . . . .	1.54	1.45
<i>o</i> -Bromo- $\alpha$ -methylstyrene . . . . .	1.87	1.49
<i>o</i> -Iodo- $\alpha$ -methylstyrene . . . . .	1.48	1.30
<i>m</i> -Methoxy- $\alpha$ -methylstyrene . . . . .	1.65	1.23
<i>m</i> -Chloro- $\alpha$ -methylstyrene . . . . .	1.80	1.56
<i>p</i> -Methoxy- $\alpha$ -methylstyrene . . . . .	1.33	1.23
<i>p</i> -Bromo- $\alpha$ -methylstyrene . . . . .	1.45	1.49

the moments of *o*-methoxy-, *o*-fluoro-, *o*-bromo- and *o*-iodo- $\alpha$ -methylstyrene, the lowering effect is seen to be great in the case of the methoxy-, fluoro- and iodo-compound, and relatively small with the bromo-derivative.

For purposes of comparison, we have also investigated some *m*- and *p*-substituted  $\alpha$ -methyl-styrenes. It should be possible to calculate their moments from those of X by vectorial addition of 0.5 D. at angles of 60° or 120° respectively. The theoretical value for *m*-chloro- $\alpha$ -methylstyrene is 1.86, for the *p*-bromo-compound 1.32, both in good agreement with the observed figures. For the methoxy-compounds no exact calculation is possible due to the spatial structure of the oxygen valencies, but the observed values show the expected magnitude. These data, however, support the dipole moment ascribed above to the unsaturated system of  $\alpha$ -methylstyrene, and show that the deviations discussed are really due to an inductive effect.

\* For the significance of the figures, see page 1319.

<sup>a</sup> All the materials were prepared as follows :

The dehydration of the carbinols which, owing to their inclination to spontaneous dehydration, could not always be isolated in an analytically pure form, was effected by heating with acetic anhydride, following the procedure of Staudinger and Breusch (*Ber.*, 1929, 62, 442).

*o*-Tolyl-dimethyl-carbinol was prepared from magnesium (3.9 gr.), methyl iodide (24 g.) and methyl *o*-toluate (11 g.); b.p. 80°/2 mm. Yield 9.5 g. The *o*,  $\alpha$ -dimethylstyrene prepared from that carbinol with acetic anhydride (10 gr.) had b.p. 59-62°/11 mm.;  $n_D^{20} = 1.5112$  (Kay and Perkin, *J. Chem. Soc.*, 1905, 87, 1083; Tiffenau, *Annales*, [8], 1907, 10, 194; Sabatier and Murat, *Compt. rend.*, 1913, 186, 185, *Annales*, [9], 1915, 4, 273).

<sup>b</sup> Grignard, *Bull. Soc. Chim. France*, 1901, **25**, 498; *Annales*, [7], 1901, **24**, 472. B.p.  $125^\circ/8 \text{ mm}$ .

<sup>c</sup> The reaction of ethyl *o*-methoxy-benzoate (b.p.  $138\text{--}144^\circ/28 \text{ mm}$ ) (18 g.) with magnesium (5.3 g.) and methyl iodide (37 g.) gave a mixture of the carbinol and the corresponding styrene derivative, boiling at  $55\text{--}55.5^\circ/1 \text{ mm}$ . Therefore the product (10 gr.) was heated with the same quantity of acetic anhydride for 8 hours. B.p.  $56\text{--}60^\circ/1 \text{ mm}$ ; yield 4.8 g  $n_D^{25} = 1.5296$ . (Found: C, 80.8; H, 8.1;  $\text{C}_{10}\text{H}_{11}\text{O}$  requires C, 81.1; H, 8.1.) It has already been reported by Béhal and Tiffeneau (*Compt. rend.*, 1904, **139**, 140; *Bull. Soc. Chim. France* [4] 1908, **3**, 315) that the above Grignard reaction gives immediately the unsaturated compound (compare Auwers, *Annalen*, 1917, **413**, 303).

<sup>d</sup>  $\alpha$ -Fluoro-phenyl-dimethyl-carbinol, prepared in the usual manner, had b.p.  $102\text{--}104^\circ/20 \text{ mm}$ ; analysis of this substance, as well as that of the corresponding ethylenic compound gave unsatisfactory figures for carbon, obviously due to the fluorine content. (Found: C, 68.7; H, 7.1. Calc. for  $\text{C}_9\text{H}_{11}\text{OF}$ : C, 70.0; H, 7.1.) For dehydration it was necessary to heat the carbinol (7.5 g.) with acetic anhydride (12 g.) for 8 hours. The styrene boiled at  $62^\circ/28 \text{ mm}$ , and showed  $n_D^{25} = 1.5009$ . (Found: C, 77.2; H, 6.7; Calc. for  $\text{C}_9\text{H}_8\text{F}$ : C, 80.0; H, 6.7.)

<sup>e</sup> From ethyl *o*-bromo-benzoate (28 g.), magnesium (6.2 g.) and methyl iodide (36.1 g.) (*o*-bromo-phenyl)-dimethyl-carbinol (13 g.) were obtained; b.p.  $87\text{--}93^\circ/1 \text{ mm}$ . (Found: C, 51.0; H, 5.4. Calc. for  $\text{C}_9\text{H}_{11}\text{OBr}$ : C, 50.2; H, 5.1.) The treatment with acetic anhydride, even after twenty-four hours, was unsuccessful; on heating the carbinol with acetic anhydride in presence of a few drops of concentrated sulphuric acid, 4 gr. of the desired styrene derivative were obtained, boiling at  $55\text{--}65^\circ/0.9 \text{ mm}$ ;  $n_D^{25} = 1.5530$ , which gave satisfactory analytical figures. (Found: C, 54.8; H, 4.9. Calc. for  $\text{C}_9\text{H}_8\text{Br}$ : C, 54.8; H, 4.6.)

## THE PHOTO REDUCTION OF FLUORESCENT SUBSTANCES BY VISIBLE LIGHT.

BY JOSEPH WEISS.

Received 8th May, 1936.

Photo-reduction has been used for preparative purposes in the well-known investigations of Ciamician and Silber<sup>1</sup> to reduce various ketones in the presence of alcohols which are themselves oxidised to the corresponding aldehydes. According to a recent theoretical discussion,<sup>2</sup> this implies that the fluorescence of the ketones in the near ultraviolet is quenched by alcohols.

Many fluorescent substances which absorb in the visible region can similarly be reduced by the action of (visible) light in the presence of inorganic reducing substances which quench the fluorescence. Some of these reactions have been discussed already in connection with the quenching effect,<sup>3</sup> but it should be pointed out that they can also be used for preparative purposes. The photoreduction of various fluorescent dyestuffs has been studied in detail.<sup>3</sup>

The reduction is carried out by irradiating a constantly stirred aqueous solution of the dyestuff containing  $FeSO_4$  (about 1 molar) with the light of a powerful carbon arc with the exclusion of oxygen. The reaction, if made in neutral solution so that the ferric salt formed is hydrolysed and precipitated (as the basic salt), results in a quantitative reduction to the leuco-dye. By this method the following dyestuffs were readily reduced: methylene blue, thionine, brilliant-cresyl blue, eosin, uranine.

With a slight adjustment of the conditions the present method could obviously be applied to the reduction of various substances, but is practically confined to fluorescent compounds. The method has the advantage that the hydrogenation can be carried out at a low temperature and in practically neutral solution.

<sup>1</sup> *Ber.*, 1903, 36, 1575; 1910, 43, 945; 1907, 40, 2415; 1911, 44, 1280.

<sup>2</sup> J. Weiss and H. Fishgold, *Z. physik. Chem., B*, 1936, 32, 135.

<sup>3</sup> J. Weiss, *Nature*, 1935, 136, 794.

The essential processes can be described by the following scheme :

[F\* fluorescent substance]

(a) light absorption  $F + h\nu \rightarrow F^*$  (excited molecule)

(b) fluorescence  
(emission)  $F^* \rightarrow F + h\nu$

(c) photo-reduction  $F^* + Fe^{++} \rightarrow F^- + Fe^{+++}$ ;  
(quenching)

(d) re-oxidation  $F^- + Fe^{+++} \rightarrow F + Fe^{++}$

In the case of a two-step reduction, we have the

(e) semiquinone equilibrium :  $2F^- \rightleftharpoons F + F^-$ .

and finally the electrolytic dissociation equilibria :

In acid solution where the  $Fe^{+++}$  ions formed in reaction (c) are not precipitated, when the irradiation ceases these dissolved  $Fe^{+++}$  re-oxidise the leuco-dye formed during illumination [reaction (d)], and the colour re-appears. In this case we have a rapidly established photochemical oxidation-reduction equilibrium.

This effect can very easily be made visible (in the absence of oxygen) by irradiating a solution containing the fluorescent dyestuff thionine ( $\sim 10^{-5}$  molar)  $FeSO_4$  ( $\sim \frac{1}{2}$  molar) and  $H_2SO_4$  ( $\sim \frac{1}{10}$  molar) looking through a layer of the solution not less than 30 mm. thick.

Similar effects were described recently by v. Euler, Brandt and Hellström,<sup>4</sup> working with the system methylen blue—ethyl alcohol—ferrous salt, and by Weber.<sup>5</sup>

From the theoretical discussion<sup>1</sup> it follows that the amount of photo-reduction increases with increasing light intensity, and that a high concentration of the reducing agent and a long (natural) lifetime of the excited state of the fluorescent substance are favourable. The reaction is naturally not confined to ferrous salts, but may also be carried out with other reducing substances, such as sulphites and sulphides.<sup>6</sup>

In principle, every fluorescent substance can be reduced by the influence of light, in the presence of suitable reducing substances, reversibly or irreversibly. This photo-reduction is identical with the elementary process of quenching of fluorescence. The dyestuff molecule in the excited state ( $F^*$ ), which possesses<sup>2</sup> an unoccupied electronic level (due to the excitation of one electron to a higher level) can take up an electron from a reducing (quenching) substance into this level (according to reaction c). In this way the excitation energy in effect increases the electron-affinity of the dyestuff molecule ( $F$ ).

The importance of the photo-reduction by ferrous ions for the assimilation process of green plants (photo-reduction of carbon dioxide with the help of the dyestuff chlorophyll under the influence of sunlight) has been discussed previously,<sup>3</sup> and will be dealt with in detail in a paper to be published shortly in the *Journal of General Physiology*.

In conclusion I would like to thank Professor F. G. Donnan, F.R.S., for his continuous help and encouragement.

# FURTHER CONSIDERATIONS ON THE THERMODYNAMICS OF CHEMICAL EQUILIBRIA AND REACTION RATES.

BY M. G. EVANS AND M. POLANYI.

*Received 14th May, 1936.*

## 1. Linear Relationships between Chemical Free Energies.

In a previous communication<sup>1</sup> we have stated for the reaction velocity constant ( $k$ )

$$k = \frac{1}{2} K v \quad . \quad . \quad . \quad (1)$$

where  $K$  is the equilibrium constant of the transition state and  $v$  the thermal velocity of the representative point along the reaction co-ordinate.<sup>2</sup> Since variations in  $v$  are small we can interpret the general empirical relationship.<sup>3</sup>

$$\log k = \alpha \log K + \text{const.} \quad . \quad . \quad . \quad (2)$$

as relating to  $K$  instead of  $k$

$$\log K = \alpha \log K + \text{const.} \quad . \quad . \quad . \quad (3)$$

Thus, equations of the type (2) are seen to be relationships between the free energy changes of chemically analogous reactions one of them being an ordinary reaction, the other being represented by the passing of the system into the transition state.  $RT \log K$  is the free energy change of the former,  $RT \log K$  that of the latter reaction.

As might be expected from this point of view, relationships of the type (2) and (3) exist also between ordinary equilibrium constants of chemically analogous reactions. Evidence of this will be adduced in the present paper.

Looking, as we do, upon all these linear relationships as laws obtaining between the free energies of chemical reactions, we will try to give them a common explanation and, at the same time, will show that they can be further generalised and amplified.<sup>4</sup>

<sup>1</sup> *Trans. Faraday Soc.*, 1935, 31, 875.

<sup>2</sup> For a similar equation see H. Eyring, *J. Chem. Physics*, 1935, 3, 107, and Wynne-Jones and Eyring, *J. Chem. Physics*, 1935, 3, 492. Such equations represent generalisations of the transition state method in the form given by Wigner and Pelzer (*Z. physik. Chem., B*, 1932, 15, 445).

<sup>3</sup> The best known examples of this relationship have been found by Brønsted (see *Chem. Rev.*, 1928, 5, 231) for the dissociation constants of acids and bases and their catalytic activities. The origins of this discovery go back to Snethlage (*Z. Elektrochem.*, 1912, 18, 539) who first showed the parallelism between acid strength and catalytic action of acid molecules and to H. S. Taylor (*Z. Elektrochem.*, 1914, 20, 201) who first related them quantitatively. More recently it has been recognised that Brønsted's law is an example of numerous relationships of the type 2 (see A. Frumkin, *Z. physik. Chem., A*, 1932, 160, 116; Hammett *Chem. Rev.*, 1935, 17, 125, and the later part of this paper).

<sup>4</sup> A preliminary notice of the following considerations was published in *Nature*, 1936, 137, 530.

**2. Thermodynamics of the Transition State. Molecular Fields.**

The well-known laws of the thermodynamics of chemical reactions are :—

*The mass action law*

$$\log K = \sum_j \nu_j \log c_j - \sum_i \nu_i \log c_i \quad (4)$$

where the  $i$ 's constitute state 1 and the  $j$ 's state 2 of the reaction.

*The reaction isochor*

$$\left( \frac{\partial \log K}{\partial T} \right) = \frac{H_p}{RT^2} \quad (5)$$

where  $H_p$  (the heat of reaction)  $= \sum_j \nu_j (\epsilon_j + p\nu_j) - \sum_i \nu_i (\epsilon_i + p\nu_i)$ .

*Kirchhoff's law*

$$\left( \frac{\partial H}{\partial T} \right)_p = \sum_j \nu_j c_p^j - \sum_i \nu_i c_p^i \quad (6)$$

which also serves for the integration of (5) and finally *the dependence of  $K$  upon hydrostatic pressure*

$$\left( \frac{\partial \log K}{\partial p} \right)_T = \frac{1}{RT} \sum_i \nu_i V_i - \frac{1}{RT} \sum_j \nu_j V_j \quad (7)$$

A less well-known thermodynamic equation which might be considered to be the generalisation of (7) is the law

$$\left( \frac{\partial \log K}{\partial \chi} \right)_T = \frac{1}{RT} \sum_i \nu_i \beta_i - \frac{1}{RT} \sum_j \nu_j \beta_j = \frac{\beta_1 - \beta_2}{RT} \quad (8)$$

Here  $\chi$  is some continuously variable parameter which can operate reversibly on the states 1 and 2, while  $\beta_1$  and  $\beta_2$  represent the derivatives with respect to  $\chi$  of the free energies of states (1) and (2) respectively.

The proof equation of (8) is as follows :

The free energy of a system of molecules each species behaving ideally is

$$\phi = \sum_i n_i (\phi_i + RT \log c_i),$$

where  $n_i$  represents the number of gram molecules of species  $i$ ,

$$c_i = \frac{n_i}{\sum_i n_i + \sum_j n_j}$$

and  $\phi_i$  the standard free energy of 1 gram molecule of  $i$  under standard condition of temperature and  $\chi$  where  $\chi$  includes hydrostatic pressure and all other possible parameters such as electric and magnetic fields, etc.

$$\phi_i = \epsilon_i + \chi \beta_i - TS_i.$$

a change in the electrode potential, and (3) a change in  $\chi$  caused by a continuous change in the nature of the solvent. Of these cases the only one which is applicable free from hypothesis with respect to  $\chi$  is realised when  $\chi = \pi$ . We have then equation (7) for equilibrium and

$$\frac{\partial \log k}{\partial \pi} = \frac{V_1 - V_r}{RT} \quad (7a)$$

for reaction velocities. Integrating (7) and (7a) on the assumption that  $V_1 - V_2$  and  $V_1 - V_r$  are independent of  $\chi$  we obtain

$$\log K = \frac{(V_1 - V_2)}{RT} \pi + \text{const.} \quad (10)$$

$$\log k = \frac{(V_1 - V_r)}{RT} \pi + \text{const.} \quad (10a)$$

We have discussed the experimental evidence for (10a) in our previous paper; more recent measurements<sup>6</sup> on the influence of pressure on the reaction between acetic anhydride and ethylalcohol give additional confirmation of the logarithmic dependence of  $k$  on  $\pi$ .

For higher pressures the square terms in  $\pi$  whose coefficients contain the compressibilities of the two states should be introduced into equation 10 and 10a.<sup>1</sup> In this paper we restrict ourselves to the linear terms in the integrated form of equations (8) and (8a). Thus we have

$$\log K = \frac{(\beta_1 - \beta_2)}{RT} \chi + \text{const.} \quad (11a)$$

$$\log k = \frac{(\beta_1 - \beta_r)}{RT} \chi + \text{const.} \quad (11b)$$

The second example of a continuous variation of  $\chi$  is realised when  $\chi$  is the electrode potential  $\epsilon$ . (11a) then becomes the Helmholtz-Nernst equation in which  $(\beta_1 - \beta_2)$  is  $1/F$  and  $\epsilon$  is the equilibrium potential.

On the other hand (11b) takes on the form of the Tafel's equation for the current  $i_1$  passing in the direction  $1 \rightarrow 2$  as a function of the electrode potential  $\epsilon$ .

$$\begin{aligned} \log i_1 &= \alpha(\epsilon/FRT) + \text{const.} \\ \alpha &= \beta_1 - \beta_r \end{aligned} \quad (12b)$$

Equations (10), (11) and (12) are examples of linear relationships between free energies in which the equilibrium constant on the left-hand side and the variable parameter multiplied by a constant on the right-hand side are different measures of the free energy. It is also clear that further relationships arise from a pair of equations (a) and (b) by eliminating  $\chi$ . In doing this we will assume that the equations (a) and (b) refer to the same reaction. We have then

$$\log k_x = \alpha \log K_x + \text{const.} \quad (13)$$

where the subscript  $\chi$  indicates that this variable has the same value for both sides of the equation. We also obtain

$$\alpha = \frac{\beta_1 - \beta_r}{\beta_1 - \beta_2} \quad (14)$$

and recognise that if the derivative of the free energy of the transition state  $\beta_r$  lies intermediate between the derivatives referring to the initial and final states,  $\beta_1$  and  $\beta_2$ , we have  $\alpha < 1$ .

<sup>6</sup> *Proc. Roy. Soc., A*, 1936, 184, 684.

The influence of hydrostatic pressure on a reaction of the type  $A + B \rightarrow AB$  is an example of a case in which  $\alpha < 1$ . Here the volume of the transition state  $V_\tau$  might be expected to be intermediate between  $V_1$  and  $V_2$ . In the more detailed discussion of our previous communication we have also explained that  $V_\tau$  is only slightly greater than  $V_2$ .

The measurements of Perrin, Gibson and Williams<sup>6</sup> show that the equilibrium of the reaction methylbenzylaniline + allylbromide  $\rightarrow$  phenylbenzylmethylallyl ammoniumbromide is changed by hydrostatic pressure to a greater extent than is the velocity constant, in consequence of which hydrostatic pressure is found to decelerate the reverse reaction, which means  $\alpha < 1$ .

Our expectation that the value of  $V_\tau$  while lying between  $V_1$  and  $V_2$  is much nearer to the latter value ( $\alpha \sim 1$ ) is borne out by the fact that the deceleration for the back reaction is only 1.5 fold for 3000 atm. increase in pressure, while for the forward reaction the acceleration is 5 fold for the same pressure change.

If for a reaction of this type the volumes  $V_1$  and  $V_2$  have been measured it can be predicted that  $\frac{\partial \log k}{\partial \chi}$  will be less than, but almost equal to  $(V_1 - V_2)/RT$ .

Brönsted's treatment of the influence of electrolytes on reaction velocity which, as stated in our previous communication, represents one of the origins of the present theory can also be expressed in the form of equation (8a). Substituting the concentration  $c$  of an added electrolyte for  $\chi$

$$\frac{\partial \log K}{\partial c} = \frac{\beta_1 - \beta_2}{RT} \quad . \quad . \quad . \quad (16)$$

where  $(\beta_1 - \beta_2)$  now means the change of the logarithms of the activity coefficients  $f$  of the states (1) and (2) with change in concentration.

$$\beta_1 = - \frac{\partial \log f_1}{\partial c}.$$

Again the equilibrium constant may refer to the equilibrium between the initial and final states of the reaction or between the initial and transition states; in which case,  $\beta_\tau = - \frac{\partial \log f_\tau}{\partial c}$  where  $f_\tau$  is equivalent to the activity coefficient of the "active complex" which Brönsted assumes. If  $\beta_1$ ,  $\beta_2$  and  $\beta_\tau$  are good constants we have for the integrated forms of (16)

$$\log K = \frac{(\beta_1 - \beta_2)}{RT} c + \text{const.}$$

$$\log k = \frac{(\beta_1 - \beta_\tau)}{RT} c + \text{const.}$$

From which, by the elimination of  $c$ , an equation of the form (2) can be obtained.

Similar equations might be suggested for the addition of non-electrolytes, or the progressive replacement of the solvent by another, perfectly miscible solvent.

#### 4. Linear Relationships Accompanying Structural Changes and Series of Different Solvents.

Consider a series of chemical equilibria, *i.e.*, a set of reactions which are closely related chemically, *e.g.*, the hydrolytic equilibria of the different substituted phenyl acetates. We assume that the series of equilibrium constants  $K_1, K_2 \dots K_j \dots$  arises according to equation (8a) by a steadily changing parameter  $\chi$  which assumes successive values  $\chi_1, \chi_2, \dots \chi_j \dots$ .

At this stage we leave the nature of  $\chi$  undefined, nor can we say what the physical meaning of the corresponding values of  $\beta$  may be. We only wish to show that these considerations lead to an explanation of the linear relationships mentioned in Section 1. For this purpose we extend the argument to a second series of reactions chemically related to the first.

Consider, for example, the equilibrium constants of the substituted phenyl acetates and of the same substituted series of benzoyl acetates. If the equilibrium constants for members of the first series are  $K_1^A, K_2^A \dots K_j^A \dots$  and for the second series  $K_1^B, K_2^B \dots K_j^B$  and moreover if we make the essential assumption that

$$\frac{\chi_1^A}{\chi_1^B} = \frac{\chi_2^A}{\chi_2^B} = \dots = \frac{\chi_j^A}{\chi_j^B} = \dots = q$$

where  $q$  is a constant, we obtain

$$\log K_i^A = \alpha \log K_i^B + \text{const.} \quad (i = 1, 2, \dots j \dots) \quad (17)$$

where 
$$\alpha = q \frac{(\beta_1 - \beta_2)^A}{(\beta_1 - \beta_2)^B}.$$

This argument can be extended to two series of the velocity constants of closely related series by using equation (11b); we thus obtain

$$\log k_i^A = \alpha \log k_i^B + \text{const.} \quad (i = 1, 2, \dots j \dots) \quad (18)$$

where 
$$\alpha = q \frac{(\beta_1 - \beta_7)^A}{(\beta_1 - \beta_7)^B}$$

and a third type of linear relationship is derived from the combination of a series of equilibrium constants with a series of reaction velocity constants.

$$\log k_i^A = \alpha \log K_i^B + \text{const.} \quad (i = 1, 2, \dots j \dots) \quad (19)$$

where 
$$\alpha = q \frac{(\beta_1 - \beta_7)^A}{(\beta_1 - \beta_2)^B}.$$

We cannot as yet test the expressions for  $\alpha$  but we enumerate the main cases conforming to equations (17) to (19).

An example of the type expressed in equation (17) is given by Burkhardt, Ford and Singleton<sup>7</sup> where  $K_i^A$  represents the dissociation constants of a series of substituted phenyl acetic acids and the  $K_i^B$  the dissociation constants of the same series of benzoic acids.

Linear relationships of the type (18) can also be inferred from that given by Burkhardt, Ford and Singleton, since the logarithms of the velocity constants of the following reactions all give linear relationships with respect to the logarithms of the dissociation constants of the corresponding benzoic acids: acid catalysed hydrolysis of the substituted

<sup>7</sup> *J. Chem. Soc.*, 1936, p. 17.

potassium phenylsulphates, alkaline hydrolysis of the corresponding benzamides, alkaline hydrolysis of the corresponding ethylbenzoates, hydrolysis of the corresponding benzylchlorides by aqueous alcohol, alkaline hydrolysis of the corresponding ethylcinnamates, bromination of the corresponding acetophenones and the reaction

for corresponding groups X.

Equation (19) expresses Brönsted's law to which we have referred in the first section. As another example, Dimroth<sup>8</sup> related the velocity constants of oxidation of a series of hydroquinones to the equilibrium constants of the corresponding quinone-hydroquinone reaction. Further cases have been found by Hammett and the results of Burkhardt, Ford and Singleton<sup>7</sup> to which we have just referred also conform to equation (19).

If, in equation (19),  $k$  and  $K$  refer to the same reaction we obtain a special case similar to that described by equation (13) for the variations of a continuous parameter. We have shown by the example of hydrostatic pressure that the relationship between  $\frac{\partial \log k}{\partial \chi}$  and  $\frac{\partial \log K}{\partial \chi}$  referring to the same reaction is found to be considerably simplified, when the mechanism of the reaction is such that  $\beta_r$  has a value intermediate between  $\beta_1$  and  $\beta_2$  and hence  $\alpha < 1$ .

The condition  $\alpha < 1$  has been found in various other important cases. It has been much discussed as a feature of Tafel's equation governing the rate of electrolytic evolution of hydrogen and other electrode processes, and has been found in acid-base catalysis (Brönsted) as well as in other proton transfers such as hydroquinone reduction (Dimroth).

Following on the lines of theory of ionogenic processes developed by Ogg and Polanyi,<sup>9</sup> an outline of the mechanism of such proton transfers was given by Horiuti and Polanyi<sup>10</sup> which led to an explanation of  $\alpha < 1$  on the assumption that reaction rate is completely determined by the energies of the transition state. The identification of energy and free energy implied in this treatment would be correct at the absolute zero of temperature only, and otherwise requires qualifications which are discussed in Section 10 below.

At the moment we only wish to restate in thermodynamical terms the main conception of the theory. If a parameter  $\chi$  operating on a reaction

the influence of  $\chi$  is restricted to *one* of the two bonds involved, the condition that  $\beta_r$  is intermediate between  $\beta_1$  and  $\beta_2$  will be fulfilled, and we have  $\alpha < 1$  provided that  $\chi$  is approximately constant over the range of elongations occurring in the affected bond.<sup>11</sup> Variation of the

<sup>8</sup> *Z. angew. Chemie*, 1933, 46, 571.

<sup>9</sup> *Proc. Manchester Lit. Phil. Soc.*, 1933-34, 78, 41; *Trans. Faraday Soc.*, 1935, 31, 604; *ibid.*, 1935, 31, 1375.

<sup>10</sup> *Acta Physico Chemica, U.S.S.R.*, 1935, 2, 505.

<sup>11</sup> It is essential that the reaction should be of the "electron switch" type, i.e. involving a change in electronic structure such as the formation of ions or a change in the valence of one or more of the reacting partners. In the next paper of this series we will show that reactions in which changes of this type occur, affecting a number of electrons, generally lead to a small perturbation energy in the transition state. (See *Trans. Faraday Soc.*, 1935, 31, 1375.)

chemical nature of A or of C alone will generally fulfil these requirements attached to  $\chi$ , while chemical modification of B will fail to do so.

A discontinuous series of  $\chi$ 's can be represented by a *series of solvents*. Such series may conform to the linear relationships set out above. Thus, equation (17) has been found to hold by Wynne-Jones<sup>12</sup> for the equilibrium constants of the reactions

which he describes as the relative dissociation constants of the acids  $A_1H$  and  $A_2H$ ; the linear dependency of such equilibrium constants on the reciprocal of the dielectric constants of the solvent implies a linear relationship between the equilibrium constants. We shall discuss the relation to the dielectric constant at a later stage.

Dimroth<sup>13</sup> provides evidence as to the changes in velocity and equilibrium constants for a reaction occurring in a series of solvents. Although these data do not comply quantitatively with equation (19) they definitely show a close parallelism of  $\log K$  and  $\log k$ . Here again the variations of  $\log k$  are smaller than the variations of  $\log K$ , thus corresponding to  $\alpha < 1$ . Thus, it is apparent that the changes of solubility of the transition state from solvent to solvent are intermediate between those of the initial and final states.

Soper<sup>14</sup> has observed that reactions in which heteropolar substances are formed are promoted by solvents of a heteropolar nature. Soper's rule becomes understandable if we again assume that the changes in solubility of the transition are intermediate between those of the initial and final states, so that the solubility of the transition state increases with that of the final state.\*

## 5. Linear Relationships Including Heat Changes.

In equations (9) and (9a) we gave the expression for the influence of changes of the parameter  $\chi$  on the heat of reaction, and the activation energy.

Equations (9) and (9a) give on integration, assuming that  $\gamma_2 - \gamma_1$  and  $\gamma_t - \gamma_1$  are constants with respect to  $\chi$

$$\begin{aligned} H &= (\gamma_2 - \gamma_1)\chi + \text{const.} \\ Q &= (\gamma_t - \gamma_1)\chi + \text{const.} \end{aligned} \quad (20)$$

and by eliminating  $\chi$  we have

$$\begin{aligned} Q &= \alpha H + \text{const.} \\ \alpha &= (\gamma_1 - \gamma_t)/(\gamma_1 - \gamma_2). \end{aligned}$$

If  $\chi$  is the hydrostatic pressure  $\pi$  then

$$\begin{aligned} \gamma_1 - \gamma_2 &= -T \left( \frac{\partial(V_1 - V_2)}{\partial T} \right)_{\pi} + (V_1 - V_2) \\ \gamma_1 - \gamma_t &= -T \left( \frac{\partial(V_1 - V_t)}{\partial T} \right)_{\pi} + (V_1 - V_t). \end{aligned}$$

<sup>12</sup> *Proc. Roy. Soc., A*, 1933, 140, 440.

<sup>13</sup> *Lieb. Ann.*, 1910, 377, 128.

<sup>14</sup> Soper and collaborators; *J. Chem. Soc.*, 1929, 1873; 1931, 2297; *Proc. Roy. Soc., A*, 1933, 140, 58, 71; 1934, 144, 643.

\* The relationships between solubilities and chemical free energies are detailed in Section 6.

For the change in heat of reaction with pressure we require not only the volume of the initial and final states but also their expansion coefficients; while for the change in activation energy it is necessary to know the volume and expansion coefficient of the transition state. One might expect  $\left(\frac{\partial V_{\tau}}{\partial T}\right)_{\pi}$  to lie between the values for the initial and final states,

in analogy to the position of  $V_{\tau}$  between  $V_1$  and  $V_2$  discussed in Section 3.

If we compare the activation energy and the reaction velocity constant at constant values of the parameter  $\chi$

$$-\frac{Q_{\tau}}{RT} = \alpha \log k_{\tau} + \text{const.},$$

where

$$\alpha = \frac{\gamma_1 - \gamma_{\tau}}{\beta_1 - \beta_{\tau}}.$$

For  $\chi = \pi$

$$\alpha = 1 - \frac{T}{V_1 - V_{\tau}} \left( \frac{\partial(V_1 - V_{\tau})}{\partial T} \right)_{\pi}.$$

If the effect of a parameter, *e.g.*, of the hydrostatic pressure on reaction rate were restricted to changes of the activation energy, we would have  $\alpha = 1$ . Our expression for  $\alpha$  shows that there is no reason to assume that this should be generally true. We shall see in Section 9 that  $\alpha = 1$  at absolute zero only.

By eliminating  $\chi$  from equations (11a), (11b), (20) and (21) we obtain linear relationships between the heat of reaction, the activation energy, the logarithm of the equilibrium constant and the logarithm of the velocity constant of the same reaction for constant values of  $\chi$ ; a conclusion which can most easily be verified for  $\chi = \pi$ , the hydrostatic pressure.

To consider discontinuous changes in the parameter we assume that  $H_1^A, H_2^A, \dots, H_j^A, \dots$  are a series of heats of reaction for a reaction of the type A arising from the influence of a steadily changing parameter, when  $\chi$  has the values  $\chi_1, \chi_2, \dots, \chi_j, \dots$ . Now  $H_1^B, H_2^B, \dots, H_j^B$  are the heats of reaction for an analogous reaction of type B when  $\chi$  has the same values  $\chi_1, \chi_2, \dots, \chi_j, \dots$ . Again, making the assumption that the influence of  $\chi$  on the two types A and B is of the form  $\frac{H_1^A}{H_1^B} = \frac{H_2^A}{H_2^B} = \dots = \frac{H_j^A}{H_j^B} = \dots = \text{const.} = q$ , we obtain from equations (9) and (20)

$$\left. \begin{aligned} H_i^A &= \alpha H_i^B + \text{const.} \quad i = 1, 2, \dots, j, \dots \\ \alpha &= q \frac{(\gamma_1 - \gamma_{\tau})^A}{(\gamma_1 - \gamma_{\tau})^B} \end{aligned} \right\} \quad (21)$$

The extensions of this expression are:—

$$\left. \begin{aligned} Q_i^A &= \alpha Q_i^B + \text{const.} \quad i = 1, 2, \dots, j, \dots \\ \alpha &= q \frac{(\gamma_1 - \gamma_{\tau})^A}{(\gamma_1 - \gamma_{\tau})^B} \end{aligned} \right\} \quad (22)$$

relating the activation energies of the members of the two series A and B.

$$\left. \begin{aligned} Q_i^A &= \alpha H_i^B + \text{const.} \quad i = 1, 2, \dots, j, \dots \\ \alpha &= q \frac{(\gamma_1 - \gamma_{\tau})^A}{(\gamma_1 - \gamma_{\tau})^B} \end{aligned} \right\} \quad (23)$$

relating the activation energy and the heat of reaction. A special case of this is where A and B refer to the same reaction, when as before we may assume  $\frac{\chi_1^A}{\chi_1^B} = \frac{\chi_2^A}{\chi_2^B} = \dots = \frac{\chi_r^A}{\chi_r^B} = \dots = 1$  then  $\alpha = \frac{\gamma_1 - \gamma_r}{\gamma_1 - \gamma_2}$ ; in the special cases where  $\gamma_r$  lies intermediate between  $\gamma_1$  and  $\gamma_2$ ,  $\alpha$  will be  $< 1$ .

By combining equations (21), (22) and (23) for special values of the parameter  $\chi$  with those arising from (8) and (8a) for the same values of the parameter  $\chi = \chi_1, \chi_2 \dots \chi_r \dots$ , we have the following set of linear relationships between chemical free energies and heat changes in chemical reactions:

$$\left. \begin{aligned} -\frac{H_i^A}{RT} &= \alpha \log K_i^B + \text{const.} \\ \alpha &= q \frac{(\gamma_1 - \gamma_2)^A}{(\beta_1 - \beta_2)^B} \end{aligned} \right\} \dots \dots \dots (24)$$

relating the heat of reaction and the equilibrium constant;

$$\left. \begin{aligned} -\frac{Q_i^A}{RT} &= \alpha \log k_i^B + \text{const.} \\ \alpha &= q \frac{(\gamma_1 - \gamma_r)^A}{(\beta_1 - \beta_r)^B} \end{aligned} \right\} \dots \dots \dots (25)$$

relating the activation energy and the velocity constant;

$$\left. \begin{aligned} -\frac{Q_i^A}{RT} &= \alpha \log K_i^B + \text{const.} \\ \alpha &= q \frac{(\gamma_1 - \gamma_r)^A}{(\beta_1 - \beta_r)^B} \end{aligned} \right\} \dots \dots \dots (26)$$

relating the activation energies and the equilibrium constant;

$$\left. \begin{aligned} -\frac{H_i^A}{RT} &= \alpha \log k_i^B + \text{const.} \\ \alpha &= q \frac{(\gamma_1 - \gamma_2)^A}{(\beta_1 - \beta_r)^B} \end{aligned} \right\} \dots \dots \dots (27)$$

relating the heat of reaction and the velocity constant.

From the work of Wynne-Jones<sup>12</sup> we have so far only adduced the linear relationship between the logarithms of the equilibrium constants for the reaction  $A_1H + A_2^- = A_2H + A_1^-$ . He also found that  $\log K = \alpha 1/D + \text{const.}$ , where  $D$  is the dielectric constant of the medium. This result conforms with equation (24), since there is no other way of interpreting the observed influence of the dielectric constant than to set  $1/D \propto H$ , i.e. the difference in solution energies of a pair of anions  $A_1$  and  $A_2$  must be proportional to  $1/D$ . This interpretation is implied in the original discussions by Wynne-Jones and in the modified treatment given by Wootten and Hammett.<sup>13</sup> The results of Wynne-Jones naturally also conform to equation (21) which follows from (17) and (24). Further evidence with respect to equation (24) will be given in the next section which deals with the equilibria of solvents and solutes.

An indication of the validity of equation (27) is given by the evidence

<sup>13</sup> J. Amer. Chem. Soc., 1935, 57, 2289

which has been put forward in support of the theorem of Ogg and Polanyi requiring a parallelism between reaction heat and reaction velocity. Quantitative data are, however, lacking for its exact verification; this should also include a test of equation (23), which is the original form in which the theorem was obtained from considerations of the reaction mechanism (compare Section II).

Equation (25) might at first sight appear trivial since it necessarily holds in so far as the collision number is invariant. In many cases which we wish to consider the collision number is far from constant and yet, as we shall see, equation (25) holds. To bring this out it might be preferable to substitute for (25) an equivalent expression which refers explicitly to the change in collision number. We do this first with reference to the general case of equilibrium constants and heats of reaction and then make the special application to velocity constants and activation energies.

By combining equations (8a) and (9a) we obtain

$$\frac{\partial(RT \log K + H)}{\partial \chi} = (\beta_1 - \beta_2) + (\gamma_2 - \gamma_1). \quad (28)$$

If  $\beta_1, \beta_2, \gamma_1$  and  $\gamma_2$  are constant with respect to  $\chi$

$$RT \log K + H = (\delta_1 - \delta_2)\chi + \text{const.} \quad (28)$$

setting  $(\beta_1 - \gamma_1) = \delta_1$  and  $(\beta_2 - \gamma_2) = \delta_2$ .

By eliminating  $\chi$  from (28) and (20) we obtain

$$RT \log K + H = \alpha H + \text{const.} \quad (29)$$

where  $\alpha = \frac{\delta_1 - \delta_2}{\gamma_2 - \gamma_1}$ .

For discontinuous values of the parameter we have

$$\frac{S_i^A}{R} = \log K_i^A + \frac{H_i^A}{RT} = \alpha \frac{H_i^B}{RT} + \text{const.} \quad (i = 1, 2, \dots, j, \dots), \quad (30)$$

where A and B represent two types of chemically analogous reactions.

We are only interested at the moment in the form of (30) relating to equation (25), i.e. to reaction velocities and activation energies:

$$\left. \begin{aligned} \frac{s_i^A}{R} &= \log k_i^A + \frac{Q_i^A}{RT} = \alpha \frac{Q_i^B}{RT} + \text{const.} \quad (i = 1, 2, \dots, j, \dots) \\ \alpha &= q \frac{(\delta_1 - \delta_2)^A}{(\gamma_2 - \gamma_1)^B} \end{aligned} \right\} \quad (31)$$

where both in equations (30) and (31) we have assumed

$$\frac{\chi_1^A}{\chi_1^B} = \frac{\chi_2^A}{\chi_2^B} = \dots = \frac{\chi_j^A}{\chi_j^B} = \dots = q,$$

and in (31) the symbol  $s$  is used to represent the entropy change between the initial and transition states.

Equation (31) is to some extent supported by the results of Olivier<sup>10</sup> for the hydrolysis of the substituted benzylchlorides by aqueous alcohol

which we have plotted in Fig. 1 and also the work of Burkhardt, Ford

FIG. 1.

and Singleton<sup>7</sup> on the acid catalysed hydrolysis of the substituted phenyl sulphates. It is significant that both these reactions also follow the linear relationship (19) which has been deduced from the same assumptions. The joint verification of the two linear relationships tends to support the assumptions on which they are both based.

Equation (26) is already verified by the fact that both equation (19) and (25) are obeyed by the same series of substances, since from (19) and (25) we obtain (26) by expressing  $\log k$  in terms of  $\log K$ .

## 6. Relationship between Entropies and Heats of Solution.

We have reserved for a special discussion the relationship between the equilibria of solutes in different solvents. From the experimental data given in literature we have found that in this field there is linear relationship between entropy and heat of solution.

If  $H_1^A, H_2^A \dots H_j^A \dots$  are the heats of solution of substance A in a series of solvents  $i = 1, 2, \dots j \dots$  and  $K_1^A, K_2^A \dots K_j^A \dots$  are the corresponding equilibrium constants for the solution process we obtain in a manner similar to that in Section 5

$$-\frac{H_i^A}{RT} = \alpha \log K_i^A + \text{const.} \quad (i = 1, 2, \dots j \dots),$$

$$\alpha = \frac{(\gamma_1 - \gamma_2)^A}{(\beta_1 - \beta_2)^A}.$$

Similarly, if  $H_A^i, H_B^i \dots H_P^i \dots$  are the heats of solution of substances A, B, . . . P . . . in the solvent  $i$  and  $K_A^i, K_B^i \dots K_P^i \dots$  the corresponding equilibrium constants then

$$-\frac{H_P^i}{RT} = \alpha \log K_P^i + \text{const.} \quad (P = A, B, \dots),$$

$$\alpha = \frac{(\gamma_1 - \gamma_2)^i}{(\beta_1 - \beta_2)^i}.$$

We can write these equations in the form of equation (30) relating entropy and heat changes.

$$\left. \begin{aligned} \frac{S_i^A}{R} &= \alpha \frac{H_i^A}{RT_i} + \text{const.} \\ \alpha &= \frac{(\delta_1 - \delta_2)^A}{(\gamma_2 - \gamma_1)^A} \end{aligned} \right\} \dots \dots \dots (32)$$

$i = 1, 2, \dots j \dots$  while A is constant and

$$\left. \begin{aligned} \frac{S_P^i}{R} &= \alpha \frac{H_P^i}{RT} + \text{const.} \\ \alpha &= \frac{(\delta_1 - \delta_2)^i}{(\gamma_2 - \gamma_1)^i} \end{aligned} \right\} \dots \dots \dots (33)$$

$P = A, B, \dots$  while  $i$  is constant.

In Table I. we have listed the heats and entropies of solution for a number of solutes for each of which the solubilities and heats of solu-

is obeyed extremely well. The data for carbazole appear to lie on two straight lines of equal slope which cover different regions of the energy and entropy scales. Fig. 2 gives a general survey of the results listed in the tables.

Table II. comprises the heat and entropy changes of a series of solutes in the same solvent. In this case all the changes are measured taking the solutes under standard conditions in the vapour state as the zero energy and entropy. The scope of validity of equation (33) which applies to this case has been found to be limited to solutes which belong to the same chemical group. Table II. does not contain all the available material, but only a selection of data referring to such groups.

The narrower range of validity of (33) indicates that variations of the solute cannot generally be regarded as changes in a parameter with respect to which the deriva-

tives of free energy and energy are constant. In other words, while in accordance with equation (32), solubility is found to be a unique function of solution heat for a given solute in varying solvents, this is not generally so for different solutes in the same solvent. Thus it appears that the phase volume of different solutes is different in the same solvent, even if the heat of solution is the same, whereas equal heats are accompanied by equal phase volumes if a substance is dissolved in different solvents.

The following conclusion seems interesting: considering the distribution of a solute between its vapour phase and its solutions in various solvents, i.e. the solubility of the vapour in these solvents, we realise that the "thermo-neutral solubility" of the vapour which would arise if the intermolecular forces between solute and solvent

could be annulled, would be equal for any solute in all solvents, but equal only for a group of chemically related solutes when compared in the same solvent.

## 7. Collision Factors in Solution.

In our previous paper we have pointed out that a generalisation of Wigner's method of calculating "collision numbers" yields

$$k = \frac{1}{2} K v,$$

where the equilibrium constant  $K$  between the initial state and the transition state can be calculated if the atomic model of both states is completely known, for solutions the atomic model should include the structure of the solvent sheath in both states. Since our know-

ledge of the structure of solutions is as yet insufficient to enable us to calculate the entropy changes in the solvent sheath we have adopted the method of calculating first the collision number in the gas phase and then relating it through the entropies of solution of the reactants and

the transition state to the collision number in solution. This procedure has shown that the "slowness" of many reactions which has been noted by Moelwyn-Hughes and Hinshelwood<sup>17</sup> can be accounted for in the cases of association reactions by the smallness of the collision factor of these reactions calculated for the gas phase. This conclusion has received support by the observations of Wassermann<sup>18</sup> that a number of association reactions have the same abnormally low collision number in the gas phase as they have in solution.

The large variations which are known to occur in the collision number when reactions are measured in different solvents and also under the influence of hydrostatic pressure, show that the collision number in solution and in the gas phase cannot in general be the same.

In this Section we wish to deal with the influence of solution on the collision number which we assume to be known for the gas phase, by extending the argument given on this subject in our previous paper.

If  $K'$  represents the equilibrium constant in solution and  $K$  the equilibrium constant in the gas phase we have for the reaction  $A + B \rightarrow C$

$$K' = K \frac{x_C}{x_A x_B}$$

where  $x_A$ ,  $x_B$  and  $x_C$  are the solubilities of the vapours A, B and C. Or, for equilibrium constants of the transition state

$$K' = K \frac{x_T}{x_A x_B},$$

where  $x_T$  is the solubility of the transition state, and with the approximation that  $v$  is not influenced by the presence of the solvent

$$k' = k \frac{x_T}{x_A x_B}$$

in the terms used in this paper we write

$$\log k' = \log k - \frac{H_T}{RT} + \frac{S_T}{R} + \frac{H_A}{RT} - \frac{S_A}{R} + \frac{H_B}{RT} - \frac{S_B}{R}$$

$$\log Z' = \log Z + \frac{S_T}{R} - \frac{S_A}{R} - \frac{S_B}{R}$$

where  $Q' = Q + H_T - H_A - H_B$

where  $Z'$  and  $Z$  are the collision numbers in solution and in the gas phase respectively.

For a numerical comparison of  $Z'$  and  $Z$  we introduce the unit of mol./litre both for the gas phase and solution, we have then

$$\log \frac{Z'}{Z} = \frac{1}{R}(S_T - S_A - S_B) - \log \frac{\Delta}{M} 10^3, \quad (34a)$$

where  $M$  and  $\Delta$  are the molecular weight and the density of the solvent.

If  $S^*$  and  $S^\circ$  are the entropy of solution and the entropy of vaporisation of the solid solute (34a) becomes

$$\log \frac{Z'}{Z} = \frac{1}{R}((S_T^* - S_T^\circ) - (S_A^* - S_A^\circ) - (S_B^* - S_B^\circ)) - \log \left( \frac{1.7\Delta}{M} 10^3 \right) \quad (34b)$$

<sup>17</sup> *J. Chem. Soc.*, 1932, p. 230.

<sup>18</sup> Wassermann, *Nature*, 1936, **137**, 497.

The tables given in the previous Section provide ample material to discuss the possible variations of  $Z'/Z$  if we assume that the substances A, B and the transition complex behave in a manner similar to the substances listed there. Taking benzene as a substance representative of a wide range of heats and entropies of solution we might assume for the moment that A, B and the complex all behave like benzene. From the values given in the table and the entropy of evaporation of benzene we calculate for two solvents taken from the extremes of the complete range, *viz.*, bromoform and phenol the values  $S/R = 8.38$  and  $5.18$  respectively. Introducing

$$\frac{S_A}{R} = \frac{S_B}{R} = \frac{S_T}{R} = 8.38,$$

we obtain  $Z'/Z = 1.2 \times 10^3$ , while for phenol with

$$\frac{S_A}{R} = \frac{S_B}{R} = \frac{S_T}{R} = 5.18,$$

we obtain  $Z'/Z = 0.89$ .

Thus we see that the collision numbers in the gas phase and in solution will in general be different and also that we might expect the occurrence of collision numbers in solution greater than those in the gas phase.<sup>19</sup>

If one of the reactants is the solvent and we assume that the reactant A and the transition state behave in the same way equation (34b) becomes

$$\log \frac{Z'}{Z} = - \frac{(S_B^\circ - S_B^s)}{R} - \log \frac{1.7\Delta}{M} 10^7.$$

When B is the solvent  $(S_B^\circ - S_B^s)$  is the entropy of vaporisation of the liquid solvent. For a large number of solvents  $\frac{(S_B^\circ - S_B^s)}{R} \sim -8$

to  $-7$ , and hence if  $\log \frac{1.7\Delta}{M} 10^7 \sim 5$   $\log \frac{Z'}{Z} \sim 3$  to  $2$ .

There are cases of reactions in which the collision number in solution has been found to be equal to that in the gas phase. Such an agreement should be considered as arising from the fortuitous cancellation of the entropy terms in equation (34). In the units in which  $S$  is expressed in (34b) this cancellation occurs when the algebraic sum of the  $S$ 's approximately equals 5. If we assume that our present knowledge of the range of  $S$ , which is presented in Fig. 3, gives us a fair estimate of the possible magnitudes of this quantity for the reactants as well as for transition states then we see that there is some probability of observing the same collision number in solution and in the gas phase, since the values of  $S/R$  range from 5 to 10 and obviously the quantity  $\left(\frac{S_T}{R} - \frac{S_A}{R} - \frac{S_B}{R}\right)$  has a considerable likelihood of being about 5 if each of the three terms lies within the range 5 to 10.

One case, however, stands out in which the agreement of the collision number in solution and in the gas phase seems to be based on a principle; it is the number of collisions between  $H_2$  and  $O_2$  measured by the magnetic conversion rate of parahydrogen, which has been found to be equal in the gas phase and in aqueous solutions.<sup>20</sup> This is a purely

<sup>19</sup> The extent to which a solvent is known to influence a collision number in some cases of "slow" reactions shows that we might expect the range of  $S$  to be greater in these cases than shown in Fig. 3.

<sup>20</sup> L. Farkas and H. Sachse, *Z. physik. Chem., B*, 1933, 23, 1; 1933, 23, 19.

"physical" collision in which the collided state is completely defined by a certain range of distances between the interacting particles; there is no fusion into a compound as represented by the transition state of a chemical reaction. The entropy of solution of a pair of gas molecule is naturally independent of their distance so long as this distance is considerable. This independence may hold even at small distances as it apparently does in aqueous solutions of  $H_2$  and  $O_2$ . It seems improbable, however, that this should be generally so in all solvents.

FIG. 3.—Key to Solutes.—1. Benzene; 2. Phenol; 3. Phenanthrene, 4. Nitrobenzene; 5. Naphthalene, 6. Benzoic acid.

If  $K_1, K_2 \dots K_j \dots$  are the equilibrium constants for a reaction  $n_A A + n_B B \dots = \nu_a a + \nu_b b \dots$  in a series of solvents 1, 2, 3  $\dots j \dots$  then  $K_1$  and  $K_j$  are related by

$$\sum_A n_A \log X_i^A - \sum_a \nu_a \log X_i^a - \sum_A n_A \log X_j^A + \sum_a \nu_a \log X_j^a + \log K^i - \log K^j = 0. \quad (35)$$

But  $\log X_i^A = -\frac{H_i^A}{RT} + \frac{S_i^A}{R}$  and similar equations hold for the reactants B  $\dots$  and a, b  $\dots$  for solvent  $i$  as well as for solvent  $j$ . Moreover, from equation (32) we have  $\frac{S_i^A}{R} = \rho_A H_i^A + \text{const.}$  for all values of A and  $i = i$  or  $j$ .

Therefore, equation (34) becomes

$$\begin{aligned} \frac{1}{RT} \sum_A n_A (H_j^A - H_i^A) - \frac{1}{RT} \sum_a \nu_a (H_j^a - H_i^a) - \sum_A \rho_A n_A (H_j^A - H_i^A) \\ + \sum_a \rho_a \nu_a (H_j^a - H_i^a) + \log K^i - \log K^j = 0. \quad (36) \end{aligned}$$

If the equilibrium constant  $K_i$  the reaction heat  $H_i$  and the heats of solution of the reactants A, B . . . a, b . . . are known for *one* solvent  $i$ , the equilibrium constant in any other solvent  $j$  can be calculated from a knowledge of the reaction heat, the heats of solution of the reactants, A, B . . . a, b . . . in that solvent and of the constants  $\rho_A, \rho_B, \dots \rho_a, \rho_b, \dots$ . The application of this theorem to ordinary equilibria is perhaps of little interest, but the analogous conclusion to be drawn for the equilibrium between the initial and the transition states seems to offer a rational approach to the study of solvent influence on reaction velocity.

Starting with a knowledge of the velocity constants  $k_i$  and  $k_j$ , the activation energies  $Q_i$  and  $Q_j$ , the heats of solution of the reactants  $H_i^A$  and  $H_j^A$  in the two solvents  $i$  and  $j$  and a knowledge of the constants  $\rho_A, \rho_B, \dots$  we can calculate the  $\rho$  constant for the transition state  $\rho_r$ .

$$\frac{1}{RT} \sum_A n_A (H_j^A - H_i^A) - \frac{1}{RT} (H_j^r - H_i^r) - \sum_A \rho_A n_A (H_j^A - H_i^A) + \rho_r (H_j^r - H_i^r) + \log k_i - \log k_j = 0.$$

We can now calculate the reaction velocity constant in any solvent provided that we know the activation energy and the heat of solution of the reactants in that solvent.

$$\log Z_j = - \sum_A \rho_A n_A (H_j^A - H_i^A) + \rho_r (H_j^r - H_i^r - Q_i + Q_j) + \log Z_i. \quad (37)$$

That is, we predict the relationship between the activation energy and the temperature independent factor  $Z$  in any solvent from solubility data and preliminary kinetic measurements in two solvents.

There are no sufficient data at present to test this relationship. We can only emphasise that this equation must hold if  $\rho_r$  exists; that is, the transition state behaves like other solute non-electrolyte substances reviewed in the previous section.

Referring once more to the discussion on page 1349, we note that if the two reactants and the transition state as solutes all behave like benzene, we might expect the change of solvent to cause variations of collision number of the order of  $10^3$  which would be accompanied by a change of 5000 cal. in the activation energy.

The variations in the entropy of solution offer a possible explanation for the fact that in some cases the temperature independent factor of monomolecular reactions deviates from the theoretical value of  $10^{13}$ . Whereas lesser values than  $10^{13}$  could be attributed to deviations from the classical dynamics assumed in the derivation of this factor,<sup>21</sup> greater values could not be hitherto explained, except where chain reactions are present. We see now that such deviations might be due to an increase in the entropy of solution accompanying the change from the initial state to the transition state.

An analogous consideration might be applied to the monomolecular changes of large molecules in general, including the gas phase. Instead of the sheath of solvent molecules causing a variation of entropy we might in this case imagine the constituent parts of the reacting molecule to adopt the same rôle. Such considerations would constitute an extension of the theory of Polanyi and Wigner<sup>21</sup> who, in their calculation of the

<sup>21</sup> *Z. physik. Chem., Haber Band*, 1928, 439.

probability of the transition state have restricted themselves to the consideration of one-, two- or three-dimensional elongation of one bond.

### 8. Continuous Changes of the Solvent.

The addition of electrolytes or non-electrolytes which do not participate in the reaction, as well as the progressive replacement of the solvent by another perfectly miscible solvent can obviously be treated on the same lines as the discontinuous change through a series of solvents. An indication of this has been given in Section 3. There is not enough experimental material to justify a further discussion at the moment.

### 9. The Influence of Viscosity on Bimolecular Reaction Rate in Solution.

Various authors have tried to correlate collision numbers to the viscosity of the medium, whereas viscosity does not enter into our theory. Now it is obvious that if the viscosity of the medium were to assume very high values, *e.g.* when the solvent passes into the vitreous state, bimolecular reactions would necessarily be slowed down almost to zero rates. Nevertheless, it can be shown that for ordinary liquids the influence of viscosity on collision number is negligible.

In our application of the transition state method we have assumed that every "representative point" passing the transition state in either direction should lead to a completion of the reaction in that direction. That is, if two particles are formed in the reaction these should be dissipated in the solution. Otherwise, if they stick together, they would have a greater tendency to enter with each other into a back reaction than has an average pair of neighbouring molecules, and the reaction could not be regarded as being fully completed.

The tendency for the newly formed particles to stick together increases with the viscosity of the solution. The effect of the viscosity becomes noticeable when two particles existing in the collided state move away so slowly from each other that they enter the back reaction before they have time to get away to a distance corresponding to the average distance of the solute molecules.

It follows that under ordinary conditions the viscosity has no influence on the collision number. Assuming, *e.g.*, an activation energy of 18,000 cal., two collided particles would react at ordinary temperatures in the course of 1 second, while in a molar solution the time required to diffuse over a distance corresponding to the average separation of the molecules, *i.e.* about  $1 \cdot 10^{-7}$  cm., would be about  $3 \cdot 10^{-4}$  sec. if the diffusion constant is of the order of  $1 \text{ day/cm}^2$ . On the other hand it is clear that if the viscosity reaches  $10^4$ -times as high values (so that the diffusion constant becomes of the order of  $10^4 \text{ day/cm}^2$  which would correspond to a vitreous state), the times of reaction and diffusion would become comparable and the latter would even become greater than the former. Under these conditions the diffusion of the particles would become the rate determining factors and the rate of the (inverse) bimolecular reaction would become independent of the activation energy and inversely proportional to the viscosity. Small activation energies of the reaction and great dilution would favour this state of affairs.

The reactions with small activation energies which are impeded by small steric factors would require a slightly different treatment which we do not wish to discuss at this stage. It is, however, easy to see that the hindrance caused by a steric factor might be taken as approximately equivalent to that caused by an activation energy.

### 10. Relationships of Energy and Entropy Based on the Nernst Theorem.

For a more detailed understanding of this relationship we first consider conditions at  $T = 0$ . According to the Nernst theorem we have

$$\left(\frac{\partial S}{\partial \chi}\right)_{T=0} = 0,$$

$$RT\left(\frac{\partial \log K}{\partial \chi}\right)_{T=0} = (\beta_1 - \beta_2)^0 = -\left(\frac{\partial H}{\partial \chi}\right)_{T=0}.$$

Assuming  $(\beta_1 - \beta_2)^0 = \text{const.}$ , we obtain for  $RT \log K$  and  $H$  as functions of  $\chi$  two straight lines at equal and opposite angles (Fig. 4), whereas  $TS$  is a horizontal.

For finite temperatures we have

$$RT\left(\frac{\partial \log K}{\partial \chi}\right)_T = (\beta_1 - \beta_2)^0 + \int_0^T \left(\frac{\partial(\beta_1 - \beta_2)}{\partial T}\right)_\chi dT, \quad (38)$$

$$-\left(\frac{\partial H}{\partial \chi}\right)_T = (\beta_1 - \beta_2)^0 + \int_0^T \left(\frac{\partial(\beta_1 - \beta_2)}{\partial T}\right)_\chi dT - T\left(\frac{\partial(\beta_1 - \beta_2)}{\partial T}\right)_\chi, \quad (39)$$

$$T\frac{\partial S}{\partial \chi} = T\left(\frac{\partial(\beta_1 - \beta_2)}{\partial T}\right)_\chi, \quad (40)$$

and after integration

$$RT \log K = (\beta_1 - \beta_2)^0 \chi + \chi \int_0^T \left(\frac{\partial(\beta_1 - \beta_2)}{\partial T}\right)_\chi dT + \text{const.} \quad (41)$$

$$-H = (\beta_1 - \beta_2)^0 \chi + \chi \int_0^T \left(\frac{\partial(\beta_1 - \beta_2)}{\partial T}\right)_\chi dT - \chi T \left(\frac{\partial(\beta_1 - \beta_2)}{\partial T}\right)_\chi + \text{const.} \quad (42)$$

$$TS = \chi T \left(\frac{\partial(\beta_1 - \beta_2)}{\partial T}\right)_\chi + \text{const.} \quad (43)$$

The magnitude of the coefficients of  $\chi$  arising from the elevation of temperature are defined graphically in Fig. 4. under the probable assumption that  $(\beta_1 - \beta_2)$  changes monotonously with temperature. The Fig. 5 shows that we might expect the sequence

$$T\left(\frac{\partial(\beta_1 - \beta_2)}{\partial T}\right)_\chi > \left\{ \int_0^T \left(\frac{\partial(\beta_1 - \beta_2)}{\partial T}\right)_\chi dT - T\left(\frac{\partial(\beta_1 - \beta_2)}{\partial T}\right)_\chi \right\} \\ > \int_0^T \left(\frac{\partial(\beta_1 - \beta_2)}{\partial T}\right)_\chi dT. \quad (44)$$

All three lines representing  $RT \ln k$ ,  $H$  and  $TS$  are seen to change their inclinations with increasing temperature in the same direction, the magnitude of the change being greatest for the  $TS$  line and smallest for the  $RT \ln k$  line. The two possible cases are a *decrease* or an *increase* of the angles with temperature, corresponding to whether  $\beta_1 - \beta_2$  increases or decreases with temperature. We have for Case I

$$-\left(\frac{\partial H}{\partial \chi}\right)^{\circ} > 0; \left\{ \int_0^T \frac{\partial(\beta_1 - \beta_2)}{\partial T} dT - T \frac{\partial(\beta_1 - \beta_2)}{\partial T} \right\} < 0,$$

$$\text{i.e. } \int_0^T T \frac{\partial^2(\beta_1 - \beta_2)}{\partial T^2} dT > 0 \quad (45)$$

or the same inequalities with the opposite sign throughout, and for Case II

$$-\left(\frac{\partial H}{\partial \chi}\right)^{\circ} > 0; \left\{ \int_0^T \frac{\partial(\beta_1 - \beta_2)}{\partial T} dT - T \frac{\partial(\beta_1 - \beta_2)}{\partial T} \right\} > 0;$$

$$\text{i.e. } \int_0^T T \frac{\partial^2(\beta_1 - \beta_2)}{\partial T^2} dT < 0 \quad (46)$$

or the same inequalities with the opposite sign throughout. As an alternative characteristic of the two cases we can introduce the influence

FIG. 4.

FIG. 5.

of  $\chi$  on the difference of heat capacities at constant  $\chi$ ,  $(c_1 - c_2)$  between states 1 and 2. Thus we have Case I or Case II according to whether the sign of  $-\left(\frac{\partial H}{\partial \chi}\right)$  is opposite or equal to that of  $\int \frac{\partial(c_1 - c_2)}{\partial \chi} dT$ .

Applying these considerations to reaction velocities,<sup>22</sup> we obtain the following features of the two cases.

Starting from  $T = 0$  and increasing the temperature, Case I exhibits two phases which are shown in Figs. 6 and 7. In Phase 1 the change of activation energy which is of opposite sign to the change of the velocity constant and of the temperature independent factor, the variations of the activation energy and the temp. ind. factor thus supplementing each other in determining the change of velocity constant. Such a complementary relationship is excluded in Case II.

<sup>22</sup> Our deductions actually refer to the equilibrium constant  $K$  between the initial and the transition states; the velocity constant is related to this by the equation  $k = \frac{1}{h} K v$ .

(see Fig. 8) where the variations of activation energy and temperature independent factor always oppose each other.

In Phase 2 of Case I. which is reached at more elevated temperatures when

$$\left\{ \int \frac{\partial(\beta_1 - \beta_2)}{\partial T} dT - T \frac{\partial(\beta_1 - \beta_2)}{\partial T} \right\} < (\beta_1 - \beta_2)^0$$

FIG. 6.

FIG. 7.

causes  $-(dH/dX)$  to pass through zero, we have equal sign in the change of activation energy and temperature independent factor so that these

FIG. 8.

two effects oppose each other in their influence on the reaction velocity. In this opposition the temperature independent factor prevails, so that the sign of its variations governs the sign in which reaction velocity changes. We shall see that this is not so when an opposition of the same two factors is present in Case II.

A sequence of reaction velocities belongs to Case II. if the changes in activation energy and temperature independent factor are of equal sign, *i.e.*, in effect oppose each other and the activation energy predominates so that its trend governs the change of reaction velocity.

The only example we know for Case I. is the effect of hydrostatic pressure on the reaction between pyridine and ethyliodide in acetone and between acetic anhydride and ethyl alcohol in toluene solution. Both the activation energy and the collision number of these reactions are in-

creased by pressure, the latter factor being predominant. This corresponds to Phase 2 of Case I.

All other reactions measured under the influence of hydrostatic pressure show the characteristics of Case II. So do all the reactions discussed in Section 5. We observe the same characteristics in the solvent-solute equilibria surveyed in Section 6; all the variations in heats and the entropies of solution oppose each other in their effects on solubility and the energy variation predominates in governing the solubility.

The following considerations suggest that Case I. is likely to be realised when  $\chi$  is an external force while Case II. is present when  $\chi$  is a force intrinsic to the reacting system.

As an example for the effect of external forces we consider the hydrostatic pressure. Supposing the reaction proceeds in the direction of smaller molar volume, we have  $-(\partial H/\partial \chi) > 0$  at low temperatures. Such a reaction being accompanied by contraction will generally lead to a reduction of the expansion coefficient and also of its differential  $\partial^2 V/\partial T^2$  with respect to temperature. It follows since

$$\int T \frac{\partial^2 V}{\partial T^2} dT = - \int \frac{\partial C}{\partial \chi} dT$$

that reactions which lead to contraction reduce the pressure dependence of the heat capacity. Hydrostatic pressure will, therefore, reduce the heat capacity of the initial state to a greater extent than that of the final or transition state, thus fulfilling the conditions of Case I.

This conclusion, however, holds only if changes in volume and in the temperature coefficients of thermal expansion change in the same direction. This certainly does not hold for associating solvents which might explain that the numerous reactions measured under hydrostatic pressure in alcoholic solutions do not conform to Case I.

Now let  $\chi$  be a measure of the attractive forces (intrinsic parameter) between the atoms taking part in the reaction leading from state 1 to state 2. Then  $-(\partial H/\partial \chi) > 0$  if the forces  $\chi$  are greater in 2 than in 1.

For a system of  $n$  quasi-elastic oscillators of equal frequency  $\nu$  the specific heat can be expressed in terms of frequencies.

$$\frac{C}{R} = \left( \frac{h\nu}{kT} \right)^2 \frac{\exp \left( \frac{h\nu}{kT} \right)}{\left( \exp \left( \frac{h\nu}{kT} \right) - 1 \right)^2}$$

An increase of the force constants tends to increase the  $\nu$ -values and hence to decrease the specific heat. According to the assumption made in the foregoing paragraph this decrease is greater for state 2 than state 1 if  $-(\partial H/\partial \chi) > 0$ . Hence  $\frac{\partial(c_1 - c_2)}{\partial \chi} > 0$ , i.e., we have an opposing sign in the variation of  $H$  and  $C_1 - C_2$  with  $\chi$  which is characteristic of Case II.

We expect, therefore, Case II. to hold whenever variations of equilibrium or reaction rates are governed by changes in the nature of the reacting system. The reacting system naturally including solvent molecules.

As already pointed out a moment ago, Case II. is actually found to hold all over the field of linear relationships surveyed in this paper where the nature of the reacting system varies by changes in intrinsic forces.

To this material we might add, following a survey by Moelwyn-Hughes,<sup>23</sup> various observations which point in the same direction although not always conforming strictly to the linear relationship. Thus Boeseken<sup>24</sup> finds that the velocity constant of many reactions can be expressed  $k = Je^{Q/C}e^{-Q/RT}$  where  $J$  and  $C$  are constants. Although this formulation implies a linear relationship between the temperature independent factor and the activation energy the agreement is only qualitative.

The above equation has been shown to apply to surface catalytic reactions<sup>25</sup> where the constant  $C$  is characteristic of the catalyst, and by Syrkin<sup>27</sup> to unimolecular reactions.

There is also evidence that for such parts of an adsorbing surface which exert high attraction forces the temperature independent factor is the smaller the higher the adsorption potential, the two factors thus counteracting each other in their effect on the adsorption equilibrium.<sup>28</sup> The extremely small values to which the entropy factor has been found to go down at high adsorption potentials is remarkable. A similar and probably essentially related phenomenon is observed in the kinetics of slow (activated) adsorption, the temperature independent factor being found to have abnormally low values.<sup>29</sup>

Although the preceding survey shows clearly that the natural variations of chemical systems do very often conform to Case II. we hesitate at this stage to lay down definitely that all such natural variations must conform to Case II. The atomic picture which we used for the deduction of this theorem is not general enough to justify more than the expectation that the characteristics of Case II. will hold as a rule, while it also indicates on what lines possible exceptions to this rule might be explained.

## 11. Relevance of Activation Energies Derived from Energy Surfaces.

The considerations of the present section should make it clear to what extent calculations of the sequence of activation energies derived from atomic mechanism can be legitimately applied to kinetic data at ordinary temperatures. The values of  $\log k$  will always follow the trend derived for the activation energies at  $T = 0$ , whereas the observed activation energies can follow an opposite trend to that calculated at  $T = 0$ , e.g. when hydrostatic pressure causes an increase in activation energy (Phase 2 of Case I.).

The inequalities (45) and (46) also show that of the three quantities  $\log k$ ,  $Q$  and  $TS$ , the coefficient of  $\chi$  arising from increase of temperature is the smallest in the expression of  $\log k$ . So even when the observed  $Q$

<sup>23</sup> Moelwyn-Hughes, *Kinetics of Reaction in Solution*, Oxford University Press, 1933, p. 167.

<sup>24</sup> *Rec. Trav. Chim.*, 1927, 46, 574.

<sup>26</sup> G. M. Schwab, *Z. physik. Chem., B*, 1929, 5, 406.

<sup>27</sup> *Z. anorg. Chem.*, 1931, 199, 28.

<sup>28</sup> Polanyi and Welke, *Z. physik. Chem., A*, 1928, 132, 371.

<sup>29</sup> H. S. Taylor, *Trans. Faraday Soc.*, 1932, 28, 137.

and  $\log k$  both change with  $\chi$  in the same direction as they would at  $T = 0$ , it is the trend of  $\log k$  (and not of  $Q$ ) which gives the better approximation to the change of  $Q$  with  $\chi$  as calculated for  $T = 0$ .

Since the trend of  $\log k$  derived for  $T = 0$  is not changed in sign by raising the temperature, we can understand that the theorem relating heats of reaction to reaction velocities and the subsequently developed theory of Bronsted's equation, as well as that of the closely related Tafel equation, which were all based on calculations referring implicitly to  $T = 0$  were found to conform satisfactorily to reaction rates measured at ordinary temperatures. It is also apparent that the *activation energies* measured at ordinary temperatures will be less likely to follow the trend derived for  $T = 0$  and that it is quite improbable that the activation energies of reactions occurring in solutions should, at ordinary temperatures, reflect quantitatively the results derived for  $T = 0$ .

This removes the difficulty to the theory of acid base catalysis recently pointed out by Bell<sup>30</sup> (who has, himself, developed an alternative form of the theory of Horiuti and Polanyi) consisting in the fact that the activation energies accompanying the variable rates are almost constant. Although this is no objection to the semi-quantitative side of the theory which for ordinary temperatures requires only parallelism between  $\log k$  and  $\log K$ , it does, nevertheless, indicate that the quantitative results of the theory require qualification corresponding to the difference between  $T = 0$  and ordinary temperatures.

### Summary.

The following are the main points of the present study.

1. Deduction of the laws of thermodynamics for the isothermic change of a parameter  $\chi$  operating on the chemical equilibrium or on the rate of a reaction. The main example for testing these laws is the case when  $\chi$  is the hydrostatic pressure. While the Arrhenius equation yields the energy and specific heat of the transition state, we can also measure the volume, the heat expansion and the compressibility of a solution of the transition state from kinetic measurements under hydrostatic pressure.

2. Extension of the scope of thermodynamics by assuming that  $\chi$  might represent the intensity of a molecular field. Although we cannot measure these intensities the laws thus derived can be tested, if it is assumed that for corresponding members (*i* or *j*) of two analogous sets of reactions A and B the values of  $\chi$  are identical, i.e.,  $\chi_i^A = \chi_i^B$ ;  $\chi_j^A = \chi_j^B$  or that at least

$$\frac{\chi_i^A}{\chi_i^B} = \frac{\chi_j^A}{\chi_j^B} = \text{const.}$$

We can then eliminate  $\chi$ . Assuming further that the linear terms of the integrated isotherm offer a satisfactory approximation over an extended range of  $\chi$  we obtain a linear relationship between values of chemical free energies  $RT \log K^A$ ,  $RT \log K^B$  . . .  $RT \log k^A$ ,  $RT \log k^B$  . . . reaction heats  $H^A$ ,  $H^B$  . . . activation energies  $Q^A$ ,  $Q^B$  . . ., in all possible combinations of these magnitudes.

3. The experimental material conforming to these relationships is ample. To this we have added one new example. We found that a linear relationship holds between the free energy of solution and the heat of solution for a given non-electrolyte solute in different solvents. A similar relationship holds for chemically related substances when different solutes are taken in the same solvent.

<sup>30</sup> *Proc. Roy. Soc., A*, 1936, **154**, 414.

4. These results have been used as an empirical framework in which to restate our previous theory of collision number in solution, and to particularise the conditions under which it will be greater or smaller than the collision number in the gas phase. We also conclude that from kinetic measurements made in two solvents and from solubility data the collision number for any other solvent can be predicted if the activation energy in that solvent is known. We have also discussed the influence of viscosity on bimolecular reaction rates and found it to be negligible.

5. The influence of a variable  $\chi$  on the reaction rate can be approximately predicted from the influence it exercises on the equilibrium, whenever the derivatives of the free energy and the energy with respect to  $\chi$  relating to the transition state lie intermediate between those relating to the initial and final states. An example can be fully worked out for verification in case that  $\chi$  is the hydrostatic pressure. For Bronsted's law of acid base catalysis and Tafel's overvoltage equation the new treatment shows that the previous theory applies strictly only to  $T = 0$  and indicates the lines on which this theory should be revised.

6. The coefficients of  $\chi$  in the integrated isotherm have been determined by use of the Nernst theorem. It follows that under the influence of  $\chi$  entropies and energies can vary according to two different types (Case I. and Case II. characterised by equations (45) and (46) respectively). An explanation is given for the fact that Case I. is only fulfilled when  $\chi$  is the hydrostatic pressure and Case II. is present when  $\chi$  is a force intrinsic to the reacting system of the sort which determines the natural variations of chemical properties. The main feature of Case II. is the opposing influence in the variations of the activation energy and the collision number which is observed in many series of chemical reactions and the analogous opposition in the variations of heat and entropy on the solubility of a solute in different solvents.

## THE OSMOTIC PRESSURE OF GUM ARABIC.

### PART II.—THE "MOLECULAR WEIGHT" WITH DIFFERENT BASES.

BY HENRY BOWEN OAKLEY.

*Received 19th May, 1936.*

In the following paper, which amplifies the preliminary work reported in 1934,<sup>1</sup> an attempt has been made to find out whether compounds of the gum with different bases have the same mean particle size or "molecular weight." This involves making sure that the part of the osmotic pressure due to the metallic cations of the gum is entirely eliminated. This has been accomplished by making measurements at low concentrations in solutions of the chloride of the appropriate base at a concentration sufficient to eliminate the ionic pressure in accordance with the theory of the Donnan<sup>2</sup> membrane equilibrium.

It is shown in a subsequent paper (Part III.)\* that the osmotic pressure of the colloid particles is only about 1 per cent. of the total

<sup>1</sup> H. B. Oakley, *Trans. Faraday Soc.*, 1935, **31**, 136.

<sup>2</sup> F. G. Donnan, *ibid.*, 82, and discussion by G. S. Hartley, 1935, p. 107.

\* To be published shortly.

osmotic pressure of the gum plus its cations as measured against pure water, so that, even if 99.9 per cent. of the ionic pressure has been eliminated, the remaining osmotic pressure will still be 10 per cent. higher than the true value for the colloid particles alone.

### Preparation of Specimens of Gum.

An improvement in preparation has been introduced by following the precautions described by L. Amy,<sup>3</sup> who showed that Gum Arabic contains an insoluble gelatinous constituent which is, however, easily peptised by a solution of gum. All gum solutions were, therefore, prepared by spreading the powdered gum on a filter paper suspended horizontally on a wire gauze and just touching the surface of water in a beaker. In a few days all the gum dissolved leaving behind about 0.1 per cent. of gelatinous constituent. Precipitation with alcohol was avoided as the above author maintains that this treatment tends to increase the insoluble fraction which may, however, still be peptised in gum solution but which cannot be removed by dialysis. About 5 per cent. solutions prepared as above, after sterilising in a water-bath for 20 minutes, were dialysed in collodion sacs against many changes of  $N/2$  solutions of the chloride of the respective bases. Silver nitrate was used for the silver gum, but in this case a preliminary dialysis against sodium nitrate was made and in this way no reduced silver was produced even after two or three weeks. Thymol was added in all cases. Such preparations showed no reduction of Fehling's solution.

With some later experiments on sodium and calcium gums, some comparative measurements were also made on specimens prepared by neutralising electro-dialysed gum. As pointed out by the present author<sup>1</sup> and confirmed by Amy,<sup>3</sup> the acid gum (unlike the neutral gum) is not stable. The later stages of the electrodialysis were, therefore, carried out in well-cooled solutions and the gum neutralised immediately the dialysis was finished.<sup>3</sup>

In all cases the gum solutions were finally dialysed against portions of the same salt solution that was to be employed in the osmometer, so that diffusible impurities were removed and the salt equilibrium already established before introduction into the osmometer.

The concentration of the gum was estimated by withdrawing the solution from the osmometer and drying *in vacuo* at 100° and subtracting the appropriate weight of salt, it being assumed that the concentration of the salt relative to the water at low concentrations of the gum was the same on both sides of the membrane.

The special low-pressure osmometer described previously<sup>1</sup> has been slightly modified for greater convenience and accuracy, as reported in a recent publication on glycogen,<sup>4</sup> special attention being paid to temperature control to less than 0.01°. All measurements were made at 25°, 20 hours being allowed in most cases for equilibrium to be established.

### Sodium Gum.

In Fig. 1  $P/C$  is plotted against  $C$  for five concentrations of NaCl; where  $P$  = osmotic pressure in mm. water and  $C$  = concentration in grams of gum per 100 grams of water. Circles represent results for gum which had not been electro-dialysed and crosses those for electro-dialysed gum subsequently neutralised with NaOH (or Ca(OH)<sub>2</sub>); they are in good agreement. The experimental error below a concentration of 0.3 per cent. becomes large, *i.e.*, over 10 per cent.

<sup>3</sup> L. Amy, *Annales de Chimie*, 1934, 2, 295.

<sup>4</sup> H. B. Oakley, F. G. Young, in press, *Biochem. Jour.*, 1936.

From the lower experimental error obtained with glycogen<sup>4</sup> it would appear that this error is to be attributed not entirely to the osmotic pressure

FIG. 1.

for  $P/C$  of about 13, and subsequently appears to drop to a value of 10, unless this is to be rejected as experimental error. With  $N/2$  NaCl the

measurements but, in part, to some inherent difficulty in obtaining reproducibility of equilibrium with the gum, and in part, to errors in the estimation of concentration, due to the small weight of gum present (20 or 30 mg.) with the much larger weight of salt. The osmotic pressure in these dilute regions amounts to only 1.0 to 2.5 mm.

The results for  $N/50$  and  $N/20$  NaCl show that these concentrations are insufficient to suppress the ionic pressure difference at a concentration of gum high enough for accurate measurement, although a limiting value of 12 to 13 appears to be approached.

The curve for  $N/10$  NaCl shows a marked flattening, between concentrations of 0.7 and 0.3 per cent., to a value

FIG. 2.

curve flattens to a value for  $P/C$  of 11.6; values at concentrations below 0.4 per cent. were not obtained, the error of weighing such small quantities of gum may be expected to increase with the amount of NaCl present.

### Calcium Gum.

Fig. 2 gives similar results for two concentrations of calcium chloride with calcium gum. This curve for  $N/10$   $\text{CaCl}_2$ , again appears to show an initial flattening to a value of 12.6 followed by a sharp fall to about 10. It will be seen that this is confirmed by several repetitions of experimental points. These regions occur at higher concentrations than is the case with sodium gum. With  $N/2$   $\text{CaCl}_2$ , the value of  $P/C$  is constant at 10.3 between concentrations of 0.3 to 0.9 per cent. of gum. The implication of these results will be discussed later.

### Comparison of Gums with Different Bases.

Before these results had been obtained experiments were made with silver, lead, potassium, lithium, sodium and calcium gums at concentrations not lower than 0.3 per cent. The concentrations of the alkali chlorides were  $N/2$ , that of silver nitrate  $N/10$ , and of lead nitrate  $N/5$ . The results are shown in Table I. Those for sodium and calcium have already been included in Figs. 1 and 2.  $P$  is expressed in mm. of water.

Too much reliance cannot be placed on the figures for silver, lead and lithium gums owing to the possibility of decomposition or partial hydration of the salts with the drying technique employed. The mean values for  $P/C$  would correspond to the initial flattening of the curve described previously, and while five of the compounds agree within 10 per cent. of each other with a value of about 11.7 the calcium gives a lower figure of 10.3

### Discussion.

If for the moment all results below 0.3 per cent. of gum are neglected the figures given in Table II. are obtained for the limiting value of  $P/C$  and the molecular weight under different conditions.  $M$  was calculated from the equation  $M = 10 RT \cdot C/P = 2.52 \times 10^6 \times C/P$  at  $25^\circ$ , where  $P$  is expressed in mm. of water.

The figures for sodium gum differ from those reported in the preliminary investigation<sup>1</sup> where the non-electro-dialysed gum gave a value of 152,000 and the electro-dialysed gum one of 245,000. The differences are attributed to the modified mode of preparation and to the fact that the present samples were kept in dialysers instead of in bottles. The agreement between electro-dialysed and non-electro-dialysed samples is considered to be good evidence that the present figures are reliable.

\* These results were not included in the averages.

TABLE II.

Salt.	Concentration.	$P/C$ .	$M$ .	
NaCl . .	$N/10$	13.3	191,000	$\pm 2.2$ per cent.
	$N/2$	11.6	217,000	$\pm 1.5$ " "
KCl . .	$N/2$	11.3	224,000	$\pm 2$ " "
CaCl <sub>2</sub> . .	$N/10$	10.3	245,000	$\pm 2$ " "
	$N/2$	10.3	245,000	$\pm 2$ " "
LiCl . .	$N/2$	12.2	206,000	$\pm 3$ " "
Pb(NO <sub>3</sub> ) <sub>2</sub> . .	$N/8$	11.7	215,000	$\pm 2$ " "
AgNO <sub>3</sub> . .	$N/10$	12.0	210,000	$\pm 6$ " "

The increase of molecular weight with increasing NaCl concentration or the higher value in the case of calcium chloride would then be attributed either to increasing aggregation of a single molecular species of gum, or to aggregation of a small quantity of a substance of lower molecular weight. In neither case does this explain the rise of  $P/C$  in  $N/10$  CaCl<sub>2</sub> to a second level of 12.6.

If the above explanation is adopted, then this singularity and the falling values of  $P/C$  in  $N/10$  NaCl below a concentration of 0.3 per cent. must be dismissed as experimental error.

If, however, these values are accepted it becomes necessary to account for the sudden fall in osmotic pressure at extremely high dilutions.

The ultracentrifuge would be the only means for obtaining accurate data at such high dilutions, and until further data have been obtained it would appear unprofitable to discuss the matter further. The fact that osmotic data for proteins agree with those obtained at high dilutions by the ultracentrifuge does not necessarily mean that this would also be the case for the very highly charged particles of gum.

### Summary.

1. From osmotic pressure measurements down to a concentration of 0.3 per cent. of gum a mean particle weight of 220,000  $\pm 10$  per cent. has been obtained for Li, Na, K, Ag and Pb gum arabic salts in  $N/2$  solutions of the alkali chlorides and  $N/10$  AgNO<sub>3</sub> and  $N/5$  Pb(NO<sub>3</sub>)<sub>2</sub>.

2. With NaCl the weight in  $N/10$  and  $N/2$  solutions was 191,000  $\pm 2.2$  per cent. and 217,000  $\pm 1.5$  per cent. respectively.

3. With CaCl<sub>2</sub> the weight was in both cases 245,000  $\pm 2$  per cent.

4. Below concentrations of 0.3 per cent. the particle weight of Na gum in  $N/10$  NaCl appears to rise to 245,000 at 0.15 per cent. It is thought that measurements of such small osmotic pressures ought to be confirmed by the ultra-centrifuge before they can be discussed profitably.

The author desires to thank Professor Donnan for his kind advice and encouragement, and Messrs. Unilever Ltd. for a grant which enabled this work to be carried out.

## SIMPLE NUMERICAL RELATIONSHIPS IN BINARY EUTECTIC MIXTURES.

BY D. STOCKDALE.

*Received 19th May, 1936.*

In a recent paper<sup>1</sup> it has been shown that in eutectics containing two metals there is a reasonable probability that the atoms are present in a comparatively simple numerical ratio. These ratios range from 1 : 2 and 2 : 3 in the case of the simple cadmium-tin and copper-silver eutectics to 4 : 19 and 8 : 47 for the more complicated copper-aluminium and copper-magnesium systems, where the eutectics are between a primary and a secondary solid solution. This relationship has been put forward empirically solely as an expression of experimental results and theoretical reasons for its existence are not yet clear. If it is the effect of some method of fitting together the two kinds of molecules, it is perhaps to be expected that the more complicated the molecule, the more limited the possible ways of fit and the simpler the ratio. Other groups of binary eutectiferous systems : salt-water, two salts with a common ion, organic compounds, are therefore examined here.

The outstanding difficulty in such an examination is the choice of data. A casual glance at critical tables may give the impression that in a certain system the eutectic ratio is exactly 1 : 3, but reference to the original work may show that only some ten points on the two branches of the liquidus curves have been determined. That is, the eutectic composition has been found by considerable extrapolation. Further, on redrawing the original curves, it may be found possible to place the eutectic at anything between 23 and 27 molecular per cent. of one of the constituents and it may become obvious that the existing evidence in favour of its falling exactly at 25 per cent. is slender. In organic chemistry, particularly, there are almost too many data and it is only too easy, by making a non-critical selection, to prove either the existence or the non-existence of simple ratios. A statistical examination of a large number of systems gives general support to the idea of simple ratios, but this result is also unsatisfactory because of the large number of ratios which may be regarded as simple, together with the uncertainty of much of the experimental work and the fact that certain of the systems have been expressed in terms of molecular percentages, critical points being given in smoothed values, 25, 40, 50 per cent., as the case may be.

In certain cases, the accuracy demanded for the establishment of a rule is beyond present experimental skill. Thus, if the weight percentage of one of the constituents in the eutectic mixture is small it is usually impossible to decide definitely whether the ratio falls at 1 : 10 (9.09 mol. per cent.) or 2 : 21 (8.70 mol. per cent.), for example, or at something indeterminate in between. This effect is intensified if the molecular weight of the constituent present in least amount is much larger than that of the other. Thus, cryohydrates frequently contain a large percentage of water and the molecular weight of the salt

<sup>1</sup> Stockdale, *Proc. Roy. Soc., A*, 1935, 152, 81.

is often many times that of water. For these reasons, *pace* Guthrie, it seems to be impossible at present either to establish or to overthrow an empirical rule by evidence obtained from a study of salt-water mixtures, and such mixtures are not further considered here.

There remain eutectics containing two salts with a common ion and binary organic eutectics. Probably the most satisfactory method of obtaining evidence about these systems is to examine the work of a limited number of investigators who have between them determined the eutectic compositions in a considerable number of systems and to reject that of those who have evidently been unaware of the serious experimental difficulties which must be overcome before reliable results in determinations of this kind can be obtained. Having once chosen the investigators, *all* their results, except those which must be discarded for the reasons discussed under cryohydrates, must be presented.

W. M. Madgin and his colleagues have determined the eutectic compositions of nine binary nitrate systems in which the eutectic contains more than ten molecular percentages of each salt. Their results are used in Table I.

Pb(NO <sub>3</sub> ) <sub>2</sub>	NH <sub>4</sub> NO <sub>3</sub>	10.43	1 : 8.59	—	—	32.5	— <sup>6</sup>
KNO <sub>3</sub>	NH <sub>4</sub> NO <sub>3</sub>	11.33	1 : 7.83	1 : 8	13.63	13.9	0.3 <sup>6</sup>

The ratios given in Table I. are of the same nature as those found for metallic eutectics.<sup>7</sup> For the metallic systems it has been shown that even though the ratios are sometimes so complicated that considered individually they are open to criticism, yet there is a definite probability that a simple ratio rule exists, and the present case appears to be parallel. The assessment of the results is rendered even more difficult by the impossibility at present of putting forward any other than an arbitrary definition of a simple ratio.

Two groups of binary organic eutectics are now considered. The first (Table II.) has been examined by Madgin and his colleagues, the second (Table III.) by N. A. Puschin and I. I. Rikovski.<sup>8</sup> The latter work was undertaken to disprove a suggestion that the two branches

of the liquidus curve of a eutectiferous system did not meet at a point ; in other words, to show that the solid eutectic mixture could not exist in contact with a liquid of variable composition. This group of experiments is therefore one of the few in which an examination of mixtures of approximately the eutectic composition was the primary purpose of the research.

<sup>9</sup> H. M. Glass, W. M. Madgin and F. Hunter, *J. Chem. Soc.*, 1934, 260.

<sup>10</sup> H. M. Glass and W. M. Madgin, *J. Chem. Soc.*, 1934, 1292.

Of the thirteen eutectic compositions considered in Tables II. and III., eleven fall at or near simple ratios. It is to be noted that in none of the original papers is the eutectic composition given nearer than half of one weight percentage. Also, because with one exception all their results are given in weight percentages, it is evident that the authors had not considered the possible existence of a rule. Therefore their determinations must be regarded as free from any subconscious bias.

The results given in Table II. must be accepted without discussion, because freezing-point data are not given and the curves therefore cannot be reconstructed. Puschin and Rikovski's curves, on the other hand, can be redrawn and some assessment made of their experimental accuracy. This has been done, and the results obtained for systems 3, 4 and 6 are in close agreement with those given in the original paper. For the other systems the conclusions are not so satisfactory. In each case it would appear that there had been a certain amount of super-cooling of one or both of the constituents and that the exact eutectic compositions are still uncertain. The fact that an exact ratio has been found in system 1 must therefore be somewhat discounted. On the other hand, if it be assumed that *m*-dinitrobenzene is a compound particularly prone to super-cooling and that neither of the phenylenediamines super-cool to an appreciable extent, then the value of 30 weight per cent. given in the original paper can be accepted for system 1 and in system 2 the eutectic would contain about 44 weight per cent. of *m*-dinitrobenzene. Thus a ratio here of 1 : 2 is not out of the question.

In the paper on metallic eutectics<sup>11</sup> it was shown that there were two ways of considering the ratios. It is as if there were two walls each built of bricks of two different colours. We can take a ratio between the numbers of bricks of different colours, as here the ratio between the numbers of constituent molecules has been considered, or we can take a ratio between the numbers of bricks in each wall, irrespective of the colour. The first kind of ratio has been named the constituent ratio, the second the phase ratio. In the latter case, allowance is made for solid solution and compound formation. In the case of metallic systems it has been shown that there cannot be exact simple ratio rules to embrace both types of ratios, but in the seven metallic systems considered the curious result was obtained that if one rule is exact the other is correct to 1 part in 200. Where the constituent ratios are somewhat complicated as 4 : 19 and 8 : 47 in the case of the copper-aluminium and copper-magnesium systems mentioned earlier, the phase ratios are often much simpler. These two systems, for example, give phase ratios of 1 : 1 and 7 : 9.

It might be that if data were available for obtaining the phase ratios for the systems considered in this paper, there would be further simplification and the four anomalous systems would fall into line. At present, as very little is known about solid solution formation in either salt or organic systems, very little can be done. It is known that an unstable compound, *m*-C<sub>6</sub>H<sub>4</sub>(NO<sub>2</sub>)<sub>2</sub>, C<sub>10</sub>H<sub>8</sub> is formed in the *m*-dinitrobenzene-naphthalene system. In this case, provided no solid solutions are formed, the phase ratio is 1 : 2 while the constituent ratio is 2 : 3. It is also known that, if one or two systems be excepted, solid solution formation in the nitrate systems given in Table I. is extremely limited, but a small solid solubility may have a large influence on the phase ratio. Thus

<sup>11</sup> Stockdale, *Proc. Roy. Soc., A*, 1935, 152, 96.

in the potassium nitrate-strontium nitrate system, if strontium nitrate can dissolve only 1.6 per cent. by weight of potassium nitrate at the temperature at which the eutectic mixture freezes, the phase ratio is 1 : 1.

The only one of these salt systems about which there is much information with regard to the solid solubilities is the potassium nitrate-ammonium nitrate system. Laybourn and Madgin find that ammonium nitrate will dissolve 8 per cent. by weight of potassium nitrate, and potassium nitrate 65 per cent. of ammonium nitrate;<sup>12</sup> that is to say, the molecular solubilities are respectively 6.44 and 70.1 per cent. The phase ratio is then 1 : 3.80, but if the eutectic were at 11.13 instead of 11.33 molecular percentages of potassium nitrate, this ratio would be exactly 1 : 4. A constituent ratio of 1 : 8 demands a eutectic containing 11.11 per cent. of potassium nitrate.

The evidence so far considered is indefinite, but it does at least suggest that simple ratio rules may exist. However, they cannot be proved or disproved until more exact experimental data are available. It is the purpose of this paper to bring forward this suggestion, in the hope that more experimental evidence may be forthcoming.

### Summary.

The suggestion that in binary eutectic mixtures the ratio between the number of molecules of each constituent is simple has been examined. Calculations have been made for certain systems containing two salts with a common ion and for certain organic mixtures. The results obtained are not conclusive, but they do at least indicate that it may be possible to establish empirically a rule of simple ratios.

## THE PHOTO-SENSITISATION OF FILMS OF POTASSIUM BY MEANS OF HYDROGEN.

By R. C. L. BOSWORTH, M.Sc., Ph.D.

*Received 21st May, 1936*

Exposure of a potassium surface to molecular hydrogen has been shown by Suhrmann<sup>1, 2</sup> to be insufficient to produce photo-electric sensitisation, and a discharge through hydrogen likewise has no effect unless the polarity of the surface is such that hydrogen ions can strike it, and then a large increase in the photo-emission is obtained. Surfaces prepared in this way have colours quite different from that of an ordinary surface and have been shown by an X-ray diffraction pattern obtained by Kluge and Rupp<sup>3</sup> to consist of small crystals of potassium hydride as well as potassium. Lukirsky and Ryanoff indeed<sup>4, 5, 6</sup> believe that the

<sup>6</sup> Ryanoff, *Z. Physik*, 1931, **77**, 325.

surface responsible for the high emission consists of a monatomic layer of potassium adsorbed on potassium hydride—a KHK surface. Lukirsky and Ryanoff have prepared these highly sensitive surfaces by allowing monatomic hydrogen prepared by dissociating hydrogen on a tungsten filament to come in contact with a potassium surface.

It is known that a potassium surface does not appear to react with molecular hydrogen, but that a clean tungsten surface instantly adsorbs hydrogen <sup>7,8</sup>. The lattice constant of a potassium surface <sup>9</sup> is 5.25 Å., while that of a tungsten surface is 2.56 Å., and the equilibrium distance apart of the two hydrogens in H<sub>2</sub> is from measurements of the moment of inertia 0.76 Å. <sup>10</sup> It appears therefore, that the fact that hydrogen will not spontaneously react with a potassium surface is connected with the fact that, to do so, the atomic components of the molecule would have to be dragged apart. Barrer <sup>11</sup> has found that for the adsorption of hydrogen on charcoal an activation energy of 13 to 15 kilocalories is required, and that as the surface concentration rises, the activation energy increases, tending finally to 30 kilocalories. Barrer has shown that his specimens of charcoal were heterogeneous, the lattice constant of the most perfect graphitised particles being 3.4 Å., and the amorphous material anything up to 4.5 Å. It is reasonable to infer, therefore, that the lower activation energies are associated with adsorption on the perfect crystals and that, when these points are saturated, still further work must be done to drag the two hydrogen atoms in the molecule far enough apart to permit them to react with the distorted amorphous lattice. It was hoped therefore, that a measure might be obtained of the energy required to make molecular hydrogen react with a potassium surface. Unfortunately this energy proved so high that even heating the potassium film to 600° K. for five minutes in the presence of hydrogen at 10<sup>-2</sup> mm. produced little or no change in its photo-electric properties, and at any higher temperature changes began to occur due to evaporation or migration of the potassium. No measure of the activation energy of the required process has therefore been obtained and the results of this work give only figures for the thresholds of the various films studied.

### Experimental.

The apparatus used consisted of two parallel tungsten filaments, one of ribbon 2 mm. wide and the other of wire 0.1 mm. thick. Around the filaments is a grid for collecting the photo-electrons and behind them a Kunsman source consisting of a filament coated with a mixture of Fe<sub>2</sub>O<sub>3</sub>, Al<sub>2</sub>O<sub>3</sub>, and K<sub>2</sub>O <sup>12, 11</sup> to provide the potassium films.

A Quartz monochromator with a pointolite source was used to provide the monochromatic light. A compensated valve bridge (Compton and Haring <sup>12</sup> modified for use with the triode electrometer valve Osram type T) was used to measure the photocurrents. The circuit was placed in an earthed steel box in order that it should be shielded from both electrostatic and electromagnetic disturbances. The lead from the grid to the photocell was similarly shielded, and the cell itself protected as much as possible from extraneous light by blackened metallic tubing.

The photo-currents at different settings of the monochromator were

obtained in the first instance by a deflection method, setting the galvanometer in the circuit to zero with the strip unilluminated. As the characteristic of the type T valve is curved over the working range this method is not strictly accurate, although the error involved in assuming linearity in the response will not be appreciable (above the limit of experimental variation) unless the photo-currents are large enough to produce a change in the anode current of the order of 100 micro-amps. In cases where this condition did not hold a compensating potentiometer circuit was set up and the photo-current to the grid balanced out against the current produced by applying a known potential from a potentiometer across a constant high resistance of  $10^{12}$  ohms, prepared by filling a capillary tube with a solution of amyl alcohol in xylene.

For theoretical purposes it is necessary to know not only the emission, but also the emission per unit of radiant energy absorbed by the surface. The relative amounts of light absorbed at different wave-lengths could be most readily determined if the photo-sensitive strip filament could be used as a bolometer filament. This has been attempted and Table I. has been obtained measuring the amount of light absorbed from out of the balance current of the bolometer bridge.

These figures indicate that the amount of light absorbed is approximately uniform over the above range of wave-lengths so that it is permissible to use the readings from the valve bridge as a measure of the photo-emission per unit of absorbed light.

5,000	0.8
4,000	0.8

### The Method of Finding Thresholds.

The old direct method consisted in plotting the emission against either the wave-length or frequency and finding the point at which the curve cuts the axis. The results obtained however depended on the accuracy with which the current could be measured; and as shown by Fowler<sup>13</sup> the intercept of the curve with the axis is only strictly definite and a measure of the threshold at absolute zero of temperature; and at all higher temperatures it is possible to get some emission at frequencies below the threshold. Fowler has developed a method of obtaining the threshold from experimental observations at frequencies near the threshold. The method as usually employed by experimentalists is summarised by the equation:

$$\log (I/T^3) = B + F(x) \quad (1)$$

Where,  $I$  is the emission per unit of absorbed radiation;  $B$  a constant depending on the units chosen;  $T$  the temperature;  $F$  a universal function, the so-called Fowler function;  $x = h(\nu - \nu_0)/kT$ ;  $\nu$  the frequency of the radiation;  $\nu_0$  the threshold frequency;  $h$  Planck's constant;  $k$  Boltzmann's constant.

Equation (1) indicates that if  $\log (I/T^3)$  be plotted against  $h\nu/kT$ , the curve obtained should be of a standard shape and when it moves horizontally by an amount  $h\nu_0/kT$  and vertically by an amount  $B$ , should fit the theoretical curve of  $\log I/T^3 = F(x)$ .

Fowler's method which has been tested and shown to be accurate for clean surfaces by several experimentalists<sup>14, 15, 16</sup> consists in finding the

<sup>13</sup> Fowler, *Physical Rev.*, 1931, 38, 45.

<sup>14</sup> Dubridge and Roehr, *ibid.*, B, 1932, 39, 99.

<sup>15</sup> Dubridge, *ibid.*, 1932, 39, 108.

<sup>16</sup> Cardwell, *ibid.*, 1930, 36, 203, 2041.

vertical shift required to make the experimental curve fit the standard curve. In practice this amounts to finding points on the experimental curve with the same slope as standard points on the theoretical curve. In short, we eliminate the constant  $B$  by a differentiation which is none the less real because it is implicit, rather than explicit; and if one were to carry out this differentiation before application of the theoretical relations, one should have a tidier and no less accurate method of arriving at  $\nu_0$ .

FIG. 1.—The function  $\phi$  at four different temperatures. The figures on the right of the ordinate refer to the L.H.S. branch of the curves.

Differentiating equation (1), we have,

$$\begin{aligned} d \log (I/T^2)/dx &= F'(x), \\ \text{or } \frac{hT}{h} d \log (I/T^2)/dx &= F'(x). \end{aligned}$$

Where  $F'$  is the first derivative of the Fowler function. In practice one deals with the wave number,

$$n = \nu/c \text{ rather than the frequency } \nu \text{ or,}$$

$$\frac{hT}{hc} \left\{ d \log (I/T^2)/dn \right\} = F' \left\{ \frac{hc}{kT} (n - n_0) \right\}.$$

Inserting numerical values and interposing,

$$n - n_0 = \frac{T}{1.432} \epsilon_1 \left\{ \frac{T}{1.432} d \log (I/T^2) / dn \right\} \quad (2)$$

$$= \phi(T, d \log (I/T^2) / dn). \quad (3)$$

Where  $\epsilon_1$  is used for the inverse function of  $F'$ . Equation (3) expresses the fact that under the circumstances in which Equation (1) holds, viz. ; for  $n$  not far from  $n_0$ ,  $n - n_0$  is a universal function of  $T$  and  $d \log (I/T^2) / dn$  no matter in what units  $I$  may be measured. Equation (2) shows how  $\phi$  is to be calculated.

If the measurements are carried out at one temperature (as in practice they usually are) ; equation (3) becomes

$$n - n_0 = \phi(T, d \log I / dn) \quad (4)$$

and, further  $\phi$  proves to be a relatively slowly varying function with respect to  $T$ , so that, if the values of  $\phi$  are calculated at  $T = 300^\circ \text{K.}$ , the tables obtained may be used on all experimental results obtained at ordinary laboratory temperatures ( $300 \pm 5^\circ \text{K.}$ ). In Fig. 1 curves are given showing  $d \log I / dn$  plotted against  $\phi$  at various temperatures ;  $200^\circ \text{K.}$ ,  $300^\circ \text{K.}$ ,  $400^\circ \text{K.}$ , and  $500^\circ \text{K.}$  For clearness the curves have been split into two sections and in the branch on the left the axis of  $\phi$  has been shifted 2,000 reciprocal centimetres vertically downwards.

The curves show that for all values of  $n$  greater than  $n_0$  the values of  $\phi$  may indeed be taken as independent of  $T$ . The variation of  $\phi$  at  $d \log I / dn = 5$  for example being only 240 cms. for a change in temperature of  $300^\circ \text{K.}$  Such a variation would only mean an error of 60 Å. at 5000 Å.

Accordingly all that is needed to use the above curves in measuring thresholds is to measure  $I$  at two different frequencies, obtain  $d \log I / dn$  and, knowing the temperature to within a few degrees, read off  $\phi$  from the appropriate curve. This  $\phi$  is equal to the mean distance of the threshold from the two points at which  $I$  was obtained.

Table II. (which expresses the results of measurements on a film of potassium on tungsten) shows how the method is to be applied. Columns (1) and (2) give the wave-length  $\lambda$ , and the experimental measurements of  $I$ , columns (3) and (4)  $\log I$  and  $n$ , column (5)  $d \log I / dn$  obtained by drawing tangents to the plot of  $\log I$  versus  $n$ , column (6) the corresponding values of  $\phi$  read off from the theoretical curves and column (7)  $n_0$  equal to

TABLE II.

$n - \phi$ . The last column shows very satisfactory consistency for all points except the first, the one furthest removed from the threshold. This consistency confirms both the accuracy of the above method and also the applicability of the Fowler relation to composite films, a point which incidentally has previously been tested and confirmed by Brady <sup>11</sup> in the case of potassium films on silver.

<sup>11</sup> Brady, *Physic. Rev.* 1834. 46, 9, 768.

## Results.

It has been possible to produce a film of standard properties in the following way. The filament was first flashed at  $2500^{\circ}\text{K.}$ , cooled and a thick deposit given to it by the Kunsman source. The bulb attached to the photo-cell was then immersed in liquid air and excess potassium over and above the equilibrium film allowed to distil off on to the cooled glass.

After about one hour the film attained constant photo-electric properties and no further change could be observed even in 24 hours. Table III. gives the properties of this film.

The film therefore has a flat selective maximum emission at 5000 Å. and a threshold measured by the method given above of 7140 Å., a figure which when compared with the 5700 Å. found by Ives and Olpin<sup>18</sup> for bulk potassium shows that the film must be a thin one and probably the monatomic layer WK.

If now this film be exposed to molecular hydrogen at a pressure of  $10^{-4}$  mm. for periods of the order of an hour or even heated to  $600^{\circ}\text{K.}$  in this gas no change whatever is produced in the emission obtained on pumping out the gas. But if the wire filament is heated in the presence of hydrogen to  $1500^{\circ}\text{K.}$  and a beam of atomic hydrogen thus fired on the strip filament, the photo-emission at all wave-lengths decreases and the threshold moves towards the ultra-violet. The

actual number of hydrogen atoms striking the surface would not be easy to compute, but the relative number may simply be obtained as the product of the pressure and the time of heating the wire filament; Table IV. indicates the progress of the threshold shift as the film is treated with atomic hydrogen.

If now over the inactive film thus produced fresh potassium is deposited and allowed to come into equilibrium with bulk potassium at liquid air temperature a highly sensitive film is produced, as Table V. indicates.

<sup>18</sup> Ives and Olpin, *Physic. Rev.*, 1929, 34, 117.

This sensitive film if treated with hydrogen will in a similar way gradually lose its emission but regain it on treatment with potassium vapour. The sensitive film above is probably a WKHK film, the insensitive one from which it was derived the WKH film. There is a way of getting films with still higher thresholds, that is by treating the filament immediately after flashing with hydrogen and then depositing the potassium over the resultant WH surface. Table VI. gives the emission.

This is probably the WHK film. It has been proved by Roberts (*loc. cit.*) that hydrogen is strongly adsorbed by tungsten and the WH surface is far more electronegative than the tungsten surface; and so, it is to be expected that any positive film adsorbed on this surface would be more strongly polarised than on tungsten. The WHK films are therefore expected to exhibit the same high sensitivity as the WOCs films studied by Kingdon<sup>10</sup>, and as the table above illustrates they do.

Collecting then the experimental results we have for the thresholds of the various surfaces studied the following figures :—

WK	7140 Å.	= 1.72	Electron Volts
WKH	5700 Å.	= 2.16	" "
WKHK	8300 Å.	= 1.49	" "
WHK	9200 Å.	= 1.34	" "

### Summary.

Monatomic films of potassium on tungsten have been prepared and examined photo-electrically. These films will not react with molecular hydrogen at room temperature or at any temperature below the volatilising point. The films do, however, react with atomic hydrogen to form a WHK surface which is capable of absorbing fresh potassium to give a sensitive WKHK surface. A still more sensitive surface may be prepared by depositing potassium on a WH surface.

A graphical method of obtaining the threshold from two readings of photo-emission of different frequencies near the threshold, is derived from Fowler's equation for photo-electric emission.

The author desires to express his gratitude to Professor E. K. Rideal for his interest in this work and for many helpful suggestions, to the Royal Commissioners for an Exhibition of 1851 and to Trinity College, Cambridge for a grant.

## THE KINETICS AND HEAT OF ADSORPTION OF ETHYLENE BY PLATINUM.

BY E. B. MAXTED AND C. H. MOON.

*Received 25th May, 1936.*

The adsorption of ethylene by catalytically active metals is of considerable importance in connection with the kinetics of hydrogenation reactions. Adsorption by metals other than platinum (*vis.* nickel, copper and iron) has already been studied by several workers,<sup>1</sup> principally

<sup>1</sup> Griffin, *J. Amer. Chem. Soc.*, 1927, **49**, 2136; Foresti, *Gazz.*, 1929, **59**, 243; Magnus and Klar, *Z. physikal. Chem.*, A, 1932, **161**, 241.

from the standpoint of the variation of the amount adsorbed with the pressure. In general, the ethylene isotherms, unlike those of hydrogen, were found to be of the continuous type; and the adsorption was, under equivalent conditions, less than that of hydrogen. For platinum, figures giving the total adsorptive power at atmospheric pressure are available,<sup>3</sup> on the basis of which ethylene may apparently be adsorbed to a slightly greater extent than hydrogen; but, in any case, few published data exist on the progress of the adsorption with time, and it has therefore been considered of interest in the present work to study the kinetics of the adsorption process.

In addition, measurements have been made of the heat of adsorption of ethylene on platinum. This subject has recently assumed importance in connection with the possible contribution<sup>4</sup> of the adsorption heat towards the activation energy of a hydrogenation reaction in its catalysed form.

It was found essential, in order to obtain consistent results, both for the kinetics and for the heat of adsorption, to take great care to free the platinum from adsorbed gases other than ethylene; and it should be emphasised that measurements carried out with platinum black which has not been previously brought into this condition possess little significance. In its freshly prepared state, platinum black contains oxygen, which may be removed by repeated treatment with pure hydrogen, in the first instance at room temperature and subsequently at 100°, each treatment being followed by prolonged degassing to remove the water formed. In the first of these treatments, hydrogen was admitted in small increments to avoid the danger of sintering. The subsequent complete elimination of the residual adsorbed hydrogen and its replacement by ethylene involves a large number of treatments with the latter gas, each treatment being followed, as before, by degassing. The progress of the replacement is most conveniently followed by observing the apparent value for the heat of adsorption of ethylene, which gradually sinks from a relatively high value—in which heat of reaction of the ethylene with residual adsorbed hydrogen is included in the apparent heat of adsorption—to a constant lower value corresponding with ethylene adsorption only.

### Experimental.

The apparatus employed is shown diagrammatically in Fig. 1. The platinum black, prepared by Mond, Ramsay and Shields' method,<sup>4</sup> which weighed 16.57 g., was contained in the calorimeter bulb, A, which, together with the first few centimetres of its connecting tube, was constructed of Pyrex glass blown as thin as possible in order to reduce its heat capacity to a minimum. We produced a bulb and connecting tube which, with a capacity of about 5 c.c., only weighed about 0.3 g. This was fused to tubing of normal wall thickness at the point shown, and was surrounded by a second bulb, B, which could be evacuated to form a small Dewar vessel, or filled with gas when a conducting enclosure was required in order to bring the platinum to the temperature of the surrounding bath. The rise in temperature during heat measurements was recorded on a rotating drum by a Moll reflecting galvanometer connected with the thermo-element, C. After trial, it was found preferable to insert this thermo-element in a

Pyrex sheath tube in such a way that it was surrounded by gas at constant pressure, the sheath being drawn out to the thinnest possible wall in the neighbourhood of the thermo-junction. By this means, the influence on the galvanometer deflection of the necessarily large change in the gas pressure—and in the conductivity of the gas surrounding the thermocouple, if this is not isolated—which occurs on and after admitting gas to the degassed metal, was avoided.

A normal vacuum calorimeter method cannot readily be used with ethylene on account of the smallness of its adsorption at low pressures; for this reason, the integral heat at constant, atmospheric pressure was measured in place of admitting small increments at a low, and continuously varying, pressure, it having previously been found that in many cases the

FIG. 1.

differential heat is independent of the amount adsorbed<sup>a</sup> and is thus identical with the adsorption heat measured when, as in the present case, a larger increment is added in one stage. The maintenance of a constant gas pressure within the calorimeter during the adsorption also renders more constant the rate of distribution of heat, by conduction, throughout the mass of adsorbent—which consists of metallic particles in incomplete contact with one another and, for the greater part, separated by gas—and simplifies the form of the heat loss factor in the observed heating curve, by the extrapolation of which the true rise in temperature is calculated.

This atmospheric pressure method was tested with hydrogen diluted

with helium or argon, and was found to give heat values consistent with those given for hydrogen on platinum by the vacuum calorimeter method. Moreover, the adsorption heat was, in conformity with previous observations, independent of the volume of hydrogen adsorbed, which could be varied by varying the degree of dilution of hydrogen with the inert gas.

All gases were carefully purified before use; ethylene by liquefaction and fractional distillation; hydrogen by desorption from palladium; and traces of oxygen were eliminated from inert gases by admixture of a small proportion of hydrogen, followed by repeated treatment with heated platinum. In some cases, the inert gases were previously subjected to prolonged sparking with oxygen in order to remove possible traces of nitrogen, followed by the removal of the excess of oxygen by flashing with phosphorus. Such sparked specimens of argon or helium gave, however, identical results with untreated specimens, since both of these gases were already in a high state of purity and, in any case, traces of nitrogen do not contribute to the observed heat effect, whereas even a small degree of contamination with oxygen leads to too high apparent heat values. The gases other than ethylene were of course only used for testing the method of heat measurement employed. Save for a preliminary stabilising period at 200°, the platinum was not subjected to a higher temperature than 100°, and all degassing was carried out at this temperature by means of a combined Hyvac and mercury vapour pump.

### Kinetics of the Adsorption.

The progress of adsorption of ethylene with time, in a typical measurement at 20°, is given in Table I. If the figures are plotted graphically, it will be seen that the course is of normal type, namely that a large part of the adsorption takes place almost instantaneously, this relatively rapid primary adsorption being followed by a much slower secondary process. This secondary adsorption follows Ward's<sup>6</sup> relationship, in which the ratio of the adsorption to the square root of the time is a constant, and, consequently, also Bangham and Burt's equation,<sup>7</sup> which involves a linear relationship between  $\log v$  and  $\log t$ . These simple linear variations do not, of course, hold for the total adsorption, which includes the distinct primary process; and their inapplicability to the total process, together with their validity for the secondary adsorption, may be regarded as additional evidence for the presence of the two distinct adsorption components. The agreement with Ward's relationship is shown in Table II., in which  $v$  is the additional adsorption after the first two minutes.

The influence of pressure on the amount adsorbed was also investigated, the isotherm being of the continuous type, as in the adsorption of ethylene on other metals. This is shown graphically in Fig. 2, which refers to the

FIG. 2.

adsorption by 16.57 g. Pt at room temperature, after one minute, at which time the primary adsorption is substantially complete and the secondary adsorption still small.

### Heat of Adsorption.

The following preliminary measurements were made with hydrogen, in order to test the method. The volume of hydrogen present in the calorimeter bulb on admission of gas to the previously degassed platinum was reduced to any desired low value by diluting the gas with argon or helium; and, in every case, the whole of the hydrogen in the bulb was completely and rapidly adsorbed by the relatively large mass of platinum employed. The rapid progress and subsequent cessation of the adsorption at a value corresponding with the available hydrogen could be followed by the gas burettes. The calorimeter\* was surrounded by a constant temperature

\* The use of a large insulated enclosing box, for all parts of the apparatus in the neighbourhood, maintained at a constant temperature by means of a small fan with appropriate heating and cooling coils (a necessary provision, in view of the so-called "gas effect," in the case of adsorption heat measurements with a vacuum calorimeter) was found not to be essential, since the results obtained with this larger enclosure were identical with those given when only the vacuum vessel containing the calorimeter was thus shielded.

enclosure. In the measurements summarised in Table III., those of Series (a) were preceded by a degassing period of 12 hours at 100°, and those of Series (b) by a similar period at room temperature. All determinations were carried out at 18°. The gas mixtures employed were made up approximately only of the composition given, since the exact adsorption was read off directly.
